How Agreement and Disagreement Evolve over Random Dynamic Networks∗

Guodong Shi, Mikael Johansson, and Karl H. Johansson†

Abstract

The dynamics of an agreement protocol interacting with a disagreement process over a common random network is considered. The model can represent the spreading of true and false information over a communication network, the propagation of faults in a large-scale control system, or the development of trust and mistrust in a society. At each time instance and with a given probability, a pair of network nodes are selected to interact. At random each of the nodes then updates its state towards the state of the other node (attraction), away from the other node (repulsion), or sticks to its current state (neglect). Agreement convergence and disagreement divergence results are obtained for various strengths of the updates for both symmetric and asymmetric update rules. Impossibility theorems show that a specific level of attraction is required for almost sure asymptotic agreement and a specific level of repulsion is required for almost sure asymptotic disagreement. A series of sufficient and/or necessary conditions are then established for agreement convergence or disagreement divergence. In particular, under symmetric updates, a critical convergence measure in the attraction and repulsion update strength is found, in the sense that the asymptotic property of the network state evolution transits from agreement convergence to disagreement divergence when this measure goes from negative to positive. The result can be interpreted as a tight bound on how much bad action needs to be injected in a dynamic network in order to consistently steer its overall behavior away from consensus.

ternet, control networks for the power grid, and information networks serving transportation systems. These networks are seldom centrally regulated, but have a strong component of distributed information processing and decision-making. While these systems are able to provide appropriate service to their users most of the time, open software and communication technologies, together with the large geographical scale of the systems, make them more exposed to faulty components, software bugs, communication failures and even purposeful injection of false data.

An interesting problem is to try to understand the amount of deficiencies that can be tolerated in the combined network before the global system performance is compromised. In this paper we tackle this challenging problem for a model inspired by agreement protocols, whose execution have been studied intensively over the last decade in a variety of settings, including load balancing in parallel computing [13, 14], coordination of autonomous agents [15, 16], distributed estimation and signal processing [17, 18], and opinion dynamics in social networks [19, 20, 21].

In this model, a pair of nodes is selected randomly at each time. The nodes update their scalar states by forming a weighted average of their own state with the state of the other node. Such a dynamic network protocol is sometimes called gossiping and its convergence is fairly well understood. To account for system defects and node misbehavior, we extend the basic gossiping model in the following way. Rather than always executing the regular update, which we call an attraction step, nodes do so with a certain probability every time they are drawn. If a node does not perform the attraction step, it randomly either updates its own state away from the other nodes state (we call this a repulsion step) or simply chooses not to perform a state update but to stick to its current value (which we call neglect). We believe that our model is one of the first to consider faulty and misbehaving nodes in gossiping algorithms. Based on our model, it is possible to analyze almost sure (a.s.) convergence to agreement and derive explicit criteria for the amount of node deficiencies that can be tolerated while still guaranteeing that all node states converge to a common value. By interpreting the repulsion step as a simple model for node misbehavior or faults, these criteria also characterize the strength or persistency of node misbehavior that is required to force the nodes to an overall disagreement.

1.2 Related Work

The structure of complex networks, and the dynamics of the internal states of the nodes in these networks, are two fundamental issues in the study of network science [7, 8].

Probabilistic models for networks such as random graphs, provide an important and convenient means for modeling large-scale systems, and have found numerous applications in various fields of science. The classical Erdős–Rényi model, in which each edge exists randomly and independently of others with a given probability, was studied in [3]. The degree distribution of the Erdős–Rényi graph is asymptotically Poisson. Generalized models were proposed in [4] and [5], for which the degree distribution satisfies certain power law that better matches the properties
of real-life networks such as the Internet. A detailed introduction to the structure of random networks can be found in [6, 7].

When a networked information is executed on top of an underlying network, nodes are endowed with internal states that evolve as nodes interact. The dynamics of the node states depend on the particular problem under investigation. For instance, the boids model was introduced in [9] to model swarm behavior and animal groups, followed by Vicsek’s model in [10]. Models of opinion dynamics in social networks were considered in [19, 20, 46] and the dynamics of communication protocols in [17]. Distributed averaging or consensus algorithms have relative simple dynamics for the network state evolution and serve as a basic model for the complex interaction between node state dynamics and the dynamics of the underlying communication graph.

Convergence to agreement for averaging algorithms have been extensively studied in the literature. Early results were developed in a general setting for studying the ergodicity of nonhomogeneous Markov chains [22, 23]. Deterministic models have been investigated in finding proper connectivity conditions that ensure consensus convergence [24, 25, 26, 27, 28, 29, 30, 31, 32]. Averaging algorithms over random graphs have also been considered [33, 34, 35, 36, 37, 38, 39].

In this paper, we use the asynchronous time model introduced in [42] to describe the randomized node interactions. Each node meets other nodes at independent time instances defined by a rate-one Poisson process, and then a pair of nodes is selected to meet at random determined by the underlying communication graph. Gossiping, in which each node is restricted to exchange data and decisions with at most one neighboring node at each time instance, has proven to be a robust and efficient way to implement distributed computations and signal processing [18, 40, 41, 42, 43, 44, 45, 46, 47]. A central problem here is to analyze if a given gossip algorithm converges to consensus, and to determine the rate of convergence of the consensus process. Karp et al. [40] derived a general lower bound for synchronous gossip. Kempe et al. [41] proposed a randomized gossip algorithm on complete graphs and determined the order of its convergence rate. Boyd et al. [42] established both lower and upper bounds for the convergence time of synchronous and asynchronous randomized gossip algorithm, and developed algorithms for optimizing parameters to obtain fast consensus. Fagnani and Zampieri discussed asymmetric gossiping in [43]. Liu et al. [44] presented a comprehensive analysis for the asymptotic convergence rates of deterministic averaging, and recently distributed gossip averaging subject to quantization constraints was studied in [45]. A nice and detailed introduction to gossip algorithms can be found in [17].

The model we introduce and analyze in this paper can be viewed as an extension to the model discussed by Acemoglu et al. [46], who used a gossip algorithm to describe the spread of misinformation in social networks. In their model, the state of each node is viewed as its belief and the randomized gossip algorithm characterizes the dynamics of the belief evolution. We believe that our model is one of the first to consider faulty and misbehaving nodes in gossip algorithms. While the distributed systems community has since long recognized the need to
provide fault tolerant systems, e.g., [55, 56], efforts to provide similar results for randomized gossiping algorithms have so far been limited. This paper aims at providing such results.

1.3 Main Contribution

The main contribution of this paper is to provide conditions for agreement convergence and disagreement divergence over random networks. To study this problem, we use a model of asynchronous randomized gossiping. At each instance, two nodes are selected to meet with a given probability. When nodes meet, normally they should update as a weighted average (attraction). Besides that, we assume that nodes can misbehave in the sense that they can take a weighted combination with one negative coefficient (repulsion), or they can stick to their current state (neglect). The potential node misbehavior essentially results in model uncertainties in the considered algorithm. Each node follows one of the three update rules at random by given probabilities whenever it is selected to meet another node. From an engineering viewpoint, this is a simple model of faults or data attacks for distributed computations. From a social network perspective, the model constitutes a non-Bayesian framework for describing how trust and mistrust of information can propagate in a society.

A fundamental question we answer is whether the network will converge to agreement (all nodes asymptotically reach the same value a.s.) or diverge to disagreement (all nodes disperse a.s.). We study both symmetric and asymmetric node updates [43]. Two general impossibility theorems are first proposed. Then, a series of sufficient and/or necessary conditions are established for the network to reach a.s. agreement convergence or disagreement divergence. In particular, under symmetric updates, a critical convergence measure is found in the sense that the asymptotic evolution of the network states transits from agreement to disagreement when this measure switches from negative to positive. This critical measure is in fact independent of the structure of the underlying communication graph. In other words, under the node dynamics considered in this paper, there is no difference if the underlying network is an Erdős–Rényi graph [3], a small-world graph [4], or a scale-free graph [5], for the network to reliably target an agreement.

1.4 Outline

The rest of the paper is organized as follows. In Section 2, we introduce the network model, the considered algorithm, the problem formulation, together with some physical motivation for the model. Section 3 presents two general impossibility theorems on a.s. agreement and disagreement, respectively. In Section 4, we discuss the model in the absence of node repulsion and give conditions for a.s. agreement convergence for both symmetric and asymmetric update steps. Section 5 presents agreement and disagreement conditions for the general model. Finally, some concluding remarks are given in Section 6.
2 Problem Definition

In this section, we present the considered network model and define the problem of interest.

We first recall some basic definitions from graph theory [2] and stochastic matrices [1]. A directed graph (digraph) \( G = (V, E) \) consists of a finite set \( V \) of nodes and an arc set \( E \subseteq V \times V \). An element \( e = (i, j) \in E \) is an arc from node \( i \in V \) to \( j \in V \). A digraph \( G \) is bidirectional if for every two nodes \( i \) and \( j \), \( (i, j) \in E \) if and only if \( (j, i) \in E \); \( G \) is weakly connected if it is connected as a bidirectional graph when all the arc directions are ignored. The converse graph, \( G^T \) of a digraph \( G = (V, E) \), is defined as the graph obtained by reversing the orientation of all arcs in \( E \). A finite square matrix \( M = [m_{ij}] \in \mathbb{R}^{n \times n} \) is called stochastic if \( m_{ij} \geq 0 \) for all \( i, j \) and \( \sum_j m_{ij} = 1 \) for all \( i \). A stochastic matrix \( M \) is doubly stochastic if also \( M^T \) is stochastic.

Let \( P = [p_{ij}] \in \mathbb{R}^{n \times n} \) be a matrix with nonnegative entries. We can associate a unique digraph \( G_P = (V, E_P) \) with \( P \) on node set \( V = \{1, \ldots, n\} \) such that \( (j, i) \in E_P \) if and only if \( p_{ij} > 0 \). We call \( G_P \) the induced graph of \( P \).

2.1 Node Pair Selection

Consider a network with node set \( V = \{1, \ldots, n\} \), \( n \geq 3 \). Let the digraph \( G_0 = (V, E_0) \) denote the underlying graph of the considered network. The underlying graph indicates potential interactions between nodes. We use the asynchronous time model introduced in [42] to describe node interactions. Each node meets other nodes at independent time instances defined by a rate-one Poisson process. This is to say, the inter-meeting times at each node follows a rate-one exponential distribution. Without loss of generality, we can assume that at most one node is active at any given instance. Let \( x_i(k) \in \mathbb{R} \) denote the state (value) of node \( i \) at the \( k \)’th meeting slot among all the nodes.

Node interactions are characterized by an \( n \times n \) matrix \( A = [a_{ij}] \), where \( a_{ij} \geq 0 \) for all \( i, j = 1, \ldots, n \) and \( a_{ij} > 0 \) if and only if \( (j, i) \in E_0 \). We assume \( A \) is a stochastic matrix. The meeting process is defined as follows.

Definition 1 (Node Pair Selection) Independent of time and node state, at time \( k \geq 0 \),

- (i) A node \( i \in V \) is drawn with probability \( 1/n \);
- (ii) Node \( i \) picks the pair \( (i, j) \) with probability \( a_{ij} \).

Note that, by the definition of the node pair selection process, the underlying graph \( G_0 \) is actually the same as \( G_A \), the induced graph of the node pair selection matrix \( A \). For \( G_0 \), we use the following assumption.

A1. (Underlying Connectivity) The underlying graph \( G_0 \) is weakly connected.
2.2 State Evolution

Suppose node \( i \) meets another node \( j \) at time \( k \). Independent of time, node states, and pair selection process, their will be three events for the iterative update for node \( i \).

(i) (Attraction) With probability \( \alpha \), node \( i \) updates as a weighted average with \( j \), marked by event \( \mathcal{A}_{ij}(k) \):

\[
x_i(k+1) = x_i(k) + T_k(x_j(k) - x_i(k)) = (1 - T_k)x_i(k) + T_kx_j(k),
\]

where \( 0 < T_k \leq 1 \) is the average weight.

(ii) (Neglect) With probability \( \beta \), node \( i \) sticks to its current state, marked by event \( \mathcal{N}_{ij}(k) \):

\[
x_i(k+1) = x_i(k).
\]

(iii) (Repulsion) With probability \( \gamma \), node \( i \) updates as a weighted average with \( j \), but with a negative coefficient, marked by \( \mathcal{R}_{ij}(k) \):

\[
x_i(k+1) = x_i(k) - S_k(x_j(k) - x_i(k)) = (1 + S_k)x_i(k) - S_kx_j(k),
\]

where \( S_k > 0 \).

Naturally we assume \( \alpha + \beta + \gamma = 1 \). Node \( j \)'s update is determined by the corresponding events \( \mathcal{A}_{ji}(k), \mathcal{N}_{ji}(k) \) and \( \mathcal{R}_{ji}(k) \), which may depend on node \( i \)'s update.

2.3 Problem

Let \( x^0 = x(k_0) = (x_1(k_0) \ldots x_n(k_0))^T \in \mathbb{R}^n \) be the initial condition, where \( k_0 \geq 0 \) is an arbitrary integer. Denote \( x(k; k_0, x^0) = (x_1(k; k_0, x_1(k_0)) \ldots x_n(k; k_0, x_n(k_0)))^T \in \mathbb{R}^n \) as the random process driven by the randomized update. When it is clear from the context, we will identify \( x(k; k_0, x^0) \) with \( x(k) \).

Introduce

\[
H(k) = \max_{i \in \mathcal{V}} x_i(k), \quad h(k) = \min_{i \in \mathcal{V}} x_i(k)
\]

as the maximum and minimum states among all nodes, respectively, and define \( \mathcal{H}(k) = H(k) - h(k) \) as the agreement measure. We make the following definition.

**Definition 2 (Agreement Convergence and Disagreement Divergence)**

(i) Agreement convergence is achieved a.s. for initial value \( x(k_0) \in \mathbb{R}^n \) if

\[
P \left( \limsup_{k \to \infty} \mathcal{H}(k) = 0 \right) = 1. \tag{4}
\]

Global agreement convergence is achieved a.s. if (4) holds for all initial values.
(ii) Disagreement divergence is achieved a.s. for initial value $x(k_0) \in \mathbb{R}^n$ if
\[ P \left( \limsup_{k \to \infty} \mathcal{H}(k) > M \right) = 1 \text{ for all } M \geq 0. \] (5)

Agreement convergence corresponds to that all states asymptotically reach the same value. Disagreement divergence does not only mean that agreement is not achieved, but that the difference of the maximum and minimum states asymptotically diverges.

2.4 Model Rationale

We illustrate and motivate the model introduced above through three application examples.

False Data Injection Attacks

Large distributed computing and control systems are vulnerable to cyber attacks. An attacker may inject false data or malicious code in the network, to mislead the nodes or even change the overall behavior of the system. The model in this paper can represent a very simple system under a cyber attack. The attraction event $\mathcal{A}_{ij}$ corresponds to normal operation of the system, under which the nodes are supposed to reach consensus. The neglect event $\mathcal{N}_{ij}$ can represent a denial-of-service attack, which block node $i$ from updating its state based on information from its neighbor $j$. The injection of malicious code in node $i$ changing its update law is modeled by the repulsion update. State agreement or disagreement indicates the failure or success of the attack. Our results in this paper allow us to explicitly characterize how large attacks a network can withstand. Various false data injection attacks for dynamical systems have recently been discussed in the literature, e.g., [49, 50, 51, 52].

Fault-Tolerant Systems

“An important goal in distributed system design is to construct the system in such a way that it can automatically recover from partial failures without seriously affecting the overall performance,” as pointed out in [53]. In our model the events $\mathcal{N}_{ij}$ and $\mathcal{R}_{ij}$ can represent node faults during a randomized computation process or in the coordination of a multi-robot system. For example, the magnitude of the repulsion parameter $S_k$ can indicate how severe a fault is. Our results show that a networked systems can sometimes be robust to quite severe faults. It is also shown that in certain cases the topology of the network does not play an essential role but the persistence and the size are more important.

Social Networks

Started from the classical work of DeGroot [19], distributed averaging similar to our model has been widely used to characterize opinion dynamics in social networks, e.g., [20, 21, 46, 48]. The
state $x_i$ of node $i$ is in these models the opinion of an individual. The individuals meet and exchange opinions. The attraction event $A_{ij}$ models the trust of node $i$ to node $j$. Whenever $A_{ij}(k)$ happens, node $i$ believes in node $j$ and therefore takes an attraction update step. The parameter $T_k$ measures the level of trust. The neglect event $N_{ij}$ models the mistrust of node $i$ to node $j$, which results in that $i$ simply ignores $j$ and sticks to its current opinion. The repulsion event $R_{ij}$ models the antagonism of node $i$ to node $j$. In this case, node $i$ takes the opposite direction to the attraction to keep a large distance to the opinion of node $j$. In this way, our model characterizes the influence of node relations to the convergence of the opinion in social networks. The idea follows the discussions on the possibilities of spread of misinformation and persistent disagreement in [46, 48]. In addition, our model also allows for opinion divergence, as indicated in the definition of disagreement divergence.

3 Impossibility Theorems

In this section, we discuss the impossibilities of agreement convergence or disagreement divergence.

A general impossibility theorem for agreement convergence is established as follows on the sequence $\{T_k\}_{k=0}^{\infty}$, i.e., on the strength of the attraction step (1).

**Theorem 1** Global agreement convergence can be achieved a.s. only if either $\sum_{k=0}^{\infty} T_k = \infty$ or $\sum_{k=0}^{\infty} (1 - T_k) = \infty$. In fact, if either $\sum_{k=0}^{\infty} T_k < \infty$ or $\sum_{k=0}^{\infty} (1 - T_k) < \infty$ holds, then for almost all initial values, we have

$$P\left(\limsup_{k \to \infty} H(k) = 0\right) = 0$$

when $k_0$ is sufficiently large.

**Proof.** The proof relies on the following well-known lemma.

**Lemma 1** Let $\{b_k\}_{k=0}^{\infty}$ be a sequence of real numbers with $b_k \in [0, 1)$ for all $k$. Then $\sum_{k=0}^{\infty} b_k = \infty$ if and only if $\prod_{k=0}^{\infty} (1 - b_k) = 0$.

Now suppose $\sum_{k=0}^{\infty} T_k < \infty$. Then $\exists K_0 \geq 0$ s.t. $T_k < 1/2, k \geq K_0$. Let node pair $(i, j)$ be selected at time $k \geq K_0$. There are two cases.

(i) Neither $x_i(k)$ nor $x_j(k)$ reaches the minimum value. Then straightforwardly we have

$$h(k+1) \leq h(k).$$

(ii) One of the two nodes, say $i$, reaches the minimum value. In this case, we have

$$x_i(k+1) = x_i(k) + T_k (x_j(k) - x_i(k)) \leq h(k) + T_k H(k)$$

if $A_{ij}(k)$ happens, and $h(k+1) \leq h(k)$ otherwise.
Thus, we obtain
\[ P\left( h(k + 1) \leq h(k) + T_k \mathcal{H}(k), \ k \geq K_0 \right) = 1. \] \tag{7}

A similar analysis leads to that
\[ P\left( H(k + 1) \geq H(k) - T_k \mathcal{H}(k), \ k \geq K_0 \right) = 1. \] \tag{8}

We see from (7) and (8) that
\[ P\left( \mathcal{H}(k + 1) \geq (1 - 2T_k) \mathcal{H}(k), \ k \geq K_0 \right) = 1. \] \tag{9}

Thus, according to (9), we conclude
\[ P\left( \limsup_{k \to \infty} \mathcal{H}(k) > 0 \right) \geq P\left( \mathcal{H}(m) > 0, \ m \geq K_0 \right) = 1 \]
for all initial conditions with \( k_0 \geq K_0 \) and \( \mathcal{H}(k_0) > 0 \). It is obvious to see that
\[ \{ x = (x_1 \ldots x_n)^T \in \mathbb{R}^n : x_1 = \cdots = x_n \} \]
is a set with measure zero in \( \mathbb{R}^n \). The desired conclusion follows.

Moreover, the conclusion for the other case \( \sum_{k=0}^{\infty} (1 - T_k) < \infty \) follows from a symmetric argument. This completes the proof. \( \Box \)

Theorem 1 establishes two general lower bounds for the attraction update regarding a.s. agreement convergence. Note that Theorem 1 does not impose any assumption on the dependence of \( \mathcal{A}_{ij}(k) \) and \( \mathcal{A}_{ji}(k) \) for the conclusion to stand.

The corresponding impossibility theorem for disagreement divergence is presented as follows.

**Theorem 2** Disagreement divergence can be achieved a.s. only if \( \prod_{k=0}^{\infty} (1 + 2S_k) = \infty \).

*Proof.* According to the definition of the randomized dynamics, it is straightforward to see that
\[ P\left( \mathcal{H}(k + 1) \leq (1 + 2S_k) \mathcal{H}(k) \right) = 1 \] \tag{10}
for all \( k \). The desired conclusion follows immediately. \( \Box \)

In the rest of the paper, we turn to the possibilities of a.s. agreement convergence and disagreement divergence.
4 Attraction vs. Neglect

In this section, we focus on the role of node attraction for the network to reach a.s. agreement convergence. In the absence of node repulsion, we show how much attraction update is enough to guarantee global a.s. agreement under symmetric or asymmetric node dynamics, respectively.

4.1 Symmetric Update

Consider the case when repulsion events never take place, i.e., nodes can only follow the attraction or neglect events. We use the following assumption, where by definition a trivial event has probability zero.

A2. *(Repulsion-Free)* \( R_{ij}(k) \) is a trivial event for all \((i, j)\) and \(k\).

This subsection focuses on the condition when the nodes’ updates are symmetric when two nodes meet, as indicated in the following assumption.

A3. *(Symmetric Attraction)* The events \( A_{ij}(k) = A_{ji}(k) \) for all \((i, j)\) and \(k\).

The main result for the symmetric update model is as follows.

**Proposition 1** Suppose A1, A2 and A3 hold. Global agreement convergence is achieved a.s. if \( \sum_{k=0}^{\infty} T_k(1 - T_k) = \infty \).

**Proof.** With A2 and A3, the considered gossip algorithm can be expressed as

\[
x(k + 1) = \Phi(k)x(k),
\]

where \( \Phi(k) \) is the random matrix satisfying

\[
P(\Phi(k) = \Phi_{(ij)} = I - T_k(e_i - e_j)(e_i - e_j)^T) = \frac{\alpha}{n}(a_{ij} + a_{ji}), \quad i \neq j
\]

with \( e_m = (0 \ldots 0 1 \ldots 0)^T \) denoting the \( n \times 1 \) unit vector whose \( m \)’th component is 1.

Define \( L(k) = \sum_{i=1}^{n} \|x_i(k) - x_{ave}\|^2 \), where \( x_{ave} = \sum_{i=1}^{n} x_i(k_0)/n \) is the average of the initial values and \( \| \cdot \| \) represents the Euclidean norm of a vector or the absolute value of a scalar.

It is easy to verify that for every possible sample and fixed instant \( k \), \( \Phi_{(ij)} \) defined in \( (12) \), is a symmetric, and doubly stochastic matrix, i.e., \( \Phi_{(ij)}1 = 1 \) and \( 1^T\Phi_{(ij)} = 1^T \).

Therefore, we have

\[
E(L(k + 1)|x(k)) = E\left( (x(k + 1) - x_{ave}1)^T(x(k + 1) - x_{ave}1) | x(k) \right)
\]

\[
= E\left( (\Phi(k)x(k) - x_{ave}1)^T(\Phi(k)x(k) - x_{ave}1) | x(k) \right)
\]

\[
= E\left( (x(k) - x_{ave}1)^T\Phi(k)^T\Phi(k)(x(k) - x_{ave}1) | x(k) \right)
\]

\[
= (x(k) - x_{ave}1)^T E(\Phi^2(k)) (x(k) - x_{ave}1)
\]

(13)
Since every possible sample of $\Phi(k)$ is doubly stochastic, each sample of $\Phi_2(k)$ is also doubly stochastic. This implies $E(\Phi(k)^T \Phi(k))$ is a stochastic matrix for all $k$, and $1$ is the eigenvector corresponding to eigenvalue $1$ of $E(\Phi^2(k))$. Thus, we can conclude from (13) that

\[
E\left(L(k + 1)|x(k)\right) \leq \lambda_2\left(E(\Phi^2(k))\right)(x(k) - x_{ave}1)^T(x(k) - x_{ave}1)
= \lambda_2\left(E(\Phi^2(k))\right)L(k),
\]

where $\lambda_2(M)$ for a stochastic matrix $M$ denotes the largest eigenvalue in magnitude excluding the eigenvalue at one.

Noticing that

\[
(I - T_k(e_i - e_j)(e_i - e_j)^T)^2 = I - 2T_k(1 - T_k)(e_i - e_j)(e_i - e_j)^T
\]

we see from (12) that

\[
P\left(\Phi^2(k) = I - 2T_k(1 - T_k)(e_i - e_j)(e_i - e_j)^T\right) = \frac{\alpha}{n}(a_{ij} + a_{ji}), \quad i \neq j.
\]

This leads to

\[
E(\Phi^2(k)) = I - 2T_k(1 - T_k)\frac{\alpha}{n}(D - (A + A^T)),
\]

where $D = \text{diag}(d_1 \ldots d_n)$ with $d_i = \sum_{j=1}^n(a_{ij} + a_{ji})$.

Note that $D - (A + A^T)$ is actually the (weighted) Laplacian of the graph $G_{A + A^T}$. With assumption A1, $G_{A + A^T}$ is a connected graph, and therefore, based on the well-known property of Laplacian matrix of connected graphs [2], we have $\lambda_2^* > 0$, where $\lambda_2^*$ is the second smallest eigenvalue of $D - (A + A^T)$. On the other hand, since $A$ is a stochastic matrix, it is straightforward to see that

\[
\sum_{j=1,j \neq i} a_{ij} + a_{ji} \leq n
\]

for all $i = 1, \ldots, n$. According to Gershgorin’s circle theorem, every eigenvalue $\lambda^*_i$ of $D - (A + A^T)$ is bounded by $2n$. Therefore,

\[
0 < 2T_k(1 - T_k)\frac{\alpha}{n}\lambda^*_i \leq 4T_k(1 - T_k) \leq 4\left(\frac{T_k + (1 - T_k)}{2}\right)^2 = 1
\]

for all $\lambda^*_i \in \sigma(D - (A + A^T))$, where $\sigma(\cdot)$ denotes the spectrum of a matrix.

Now we conclude from (16) and (13) that for all $k$,

\[
\lambda_2\left(E(\Phi^2(k))\right) = 1 - \frac{2T_k(1 - T_k)\alpha}{n}\lambda_2^*.
\]

With (14) and (19), we obtain

\[
E\left(L(k + 1)\right) \leq \prod_{i=k_0}^k \lambda_2\left(E(\Phi^2(i))\right)L(k_0) = \prod_{i=k_0}^k \left(1 - \frac{2T_k(1 - T_k)\alpha}{n}\lambda_2^*\right)L(k_0),
\]

where $\lambda_2$ denotes the largest eigenvalue of $L$ and $k_0$ is such that $L(k_0)$ is the initial state of the system.
Therefore, based on Lemma 1 and Fatou’s lemma, we have

\[ E \left( \lim_{k \to \infty} L(k) \right) \leq \lim_{k \to \infty} E(L(k)) = 0, \]

if \( \sum_{k=0}^{\infty} T_k(1 - T_k) = \infty \), where \( \lim_{k \to \infty} L(k) \) exists simply from the fact that the sequence is non-increasing. This immediately implies

\[ P \left( \lim_{k \to \infty} x_i(k) = x_{ave} \right) = 1. \]

The proof is finished. \( \square \)

There is an interesting connection between the impossibility statement Theorem 1 and Proposition 1. Let us consider a special case when \( T_i \) is monotone. It is not hard to find that if \( T_{i+1} \leq T_i \) for all \( i \), \( \sum_{k=0}^{\infty} T_k(1 - T_k) < \infty \) leads to \( \sum_{k=0}^{\infty} T_k < \infty \), while \( \sum_{k=0}^{\infty} T_k(1 - T_k) < \infty \) leads to \( \sum_{k=0}^{\infty} (1 - T_k) < \infty \) if \( T_{i+1} \geq T_i \) for all \( i \). As a result, combining Theorem 1 and Proposition 1, we have the following conclusion.

**Theorem 3** Suppose \( A_1, A_2 \) and \( A_3 \) hold. Assume that either \( T_{i+1} \leq T_i \) or \( T_{i+1} \geq T_i \) for all \( i \). Then \( \sum_{k=0}^{\infty} T_k(1 - T_k) = \infty \) is a threshold condition regarding global a.s. agreement convergence:

(i) \( P \left( \limsup_{k \to \infty} \mathcal{H}(k) = 0 \right) = 0 \) for almost all initial conditions with \( k_0 \) sufficiently large if \( \sum_{k=0}^{\infty} T_k(1 - T_k) < \infty \);

(ii) \( P \left( \limsup_{k \to \infty} \mathcal{H}(k) = 0 \right) = 1 \) for all initial conditions if \( \sum_{k=0}^{\infty} T_k(1 - T_k) = \infty \).

4.2 Asymmetric Update

In this subsection, we investigate the case when the node updates are asymmetric, as indicated by the following assumption.

**A4.** (Asymmetric Attraction) \( \mathcal{A}_{ij}(k) \cap \mathcal{A}_{ji}(k) \) is a trivial event for all \((i, j)\) and \(k\).

We present the main result for the asymmetric update model as follows.

**Proposition 2** Suppose \( A_1, A_2 \) and \( A_4 \) hold. Then global agreement convergence is achieved a.s. if

\[ \sum_{k=0}^{\infty} \left[ \prod_{s=k(n-1)}^{(k+1)(n-1)-1} T_s(1 - T_s) \right] = \infty. \]

**Proof.** Take \( k_* \geq 0 \). Denote \( a_* = \min \{ a_{ij} : a_{ij} > 0 \} \) as the lower bound of the nonzero entries of \( A \). Suppose \( i_0 \) is some node satisfying \( x_{i_0}(k_*) = h(k_*) \).

Let \( i_1 \) be a node which is connected to \( i_0 \) in graph \( G_0 \). We see that such \( i_1 \) exists based on the weak connectivity assumption \( A_1 \). With assumptions \( A_2 \) and \( A_4 \), we have

\[ P \left( \text{pair } (i_0, i_1) \text{ or } (i_1, i_0) \text{ selected, and } \mathcal{A}_{i_1i_0} \text{ happens} \right) \geq \frac{a_*}{n} \alpha. \]
Moreover, if \( \mathcal{A}_{i_1i_0} \) happens, we have

\[
x_{i_1}(k_*) + 1 = x_{i_1}(k_*) + T_{k_*}(x_{i_0}(k_*) - x_{i_1}(k_*)) \\
= T_{k_*}x_{i_0}(k_*) + (1 - T_{k_*})x_{i_1}(k_*) \\
\leq T_{k_*}h(k_*) + (1 - T_{k_*})H(k_*) \\
\leq T_{k_*}(1 - T_{k_*})h(k_*) + (1 - T_{k_*}(1 - T_{k_*})))H(k_*)
\]

and \( x_{i_0}(k_*) + 1 = x_{i_0}(k_*) \) according to assumption \( A4 \). This implies

\[
\mathbf{P}\left( x_{i_1}(k_* + 1) \leq T_{k_*}(1 - T_{k_*})h(k_*) + (1 - T_{k_*}(1 - T_{k_*})))H(k_*) \right) \geq \frac{a_*}{n} \alpha.
\]

Next, according to the weak connectivity assumption \( A1 \), another node \( i_2 \) can be found such that \( i_2 \) is connected to \( \{i_0, i_1\} \) in \( G_0^* \). There will be two cases.

(i) \( i_2 \) is connected to \( i_0 \) in \( G_0^* \). Then by a similar analysis we used for bounding \( x_{i_1}(k_* + 1) \), we obtain

\[
\mathbf{P}\left( x_{i_0}(k_* + 2) = x_{i_0}(k_*), \ x_{i_1}(k_* + 2) = x_{i_1}(k_* + 1), \ \text{and} \ x_{i_2}(k_* + 2) \leq T_{k_*+1}h(k_*) + (1 - T_{k_*+1})H(k_*) \right) \geq \frac{a_*}{n} \alpha.
\]

(ii) \( i_2 \) is connected to \( i_1 \) in \( G_0^* \). Suppose pair \( (i_1, i_2) \) or \( (i_2, i_1) \) selected, and \( \mathcal{A}_{i_2i_1} \) happens at time \( k_* + 1 \). Then we have

\[
x_{i_1}(k_* + 2) = x_{i_1}(k_* + 1)
\]

and

\[
x_{i_2}(k_* + 2) = x_{i_2}(k_* + 1) + T_{k_*+1}(x_{i_1}(k_*) - x_{i_2}(k_* + 1)) \\
\leq (1 - T_{k_*+1})H(k_*) + T_{k_*+1}\left( T_{k_*}(1 - T_{k_*})h(k_*) + (1 - T_{k_*}(1 - T_{k_*})))H(k_*) \right) \\
\leq (1 - T_{k_*+1})H(k_*) + T_{k_*+1}\left( T_{k_*}(1 - T_{k_*})h(k_*) + (1 - T_{k_*}(1 - T_{k_*})))H(k_*) \right) \\
= T_{k_*+1}T_{k_*}(1 - T_{k_*})h(k_*) + (1 - T_{k_*+1}T_{k_*}(1 - T_{k_*})))H(k_*) \\
\leq h(k_*) \prod_{k=k_*}^{k_*+1} T_k(1 - T_k) + H(k_*)\left( 1 - \prod_{k=k_*}^{k_*+1} T_k(1 - T_k) \right)
\]

conditioned that pair \( (i_0, i_1) \) or \( (i_1, i_0) \) selected, and \( \mathcal{A}_{i_1i_0} \) happens at time \( k_* \).

Noting the fact that

\[
T_{k_*}h(k_*) + (1 - T_{k_*})H(k_*) \leq h(k_*) \prod_{k=k_*}^{k_*+1} T_k(1 - T_k) + H(k_*)\left( 1 - \prod_{k=k_*}^{k_*+1} T_k(1 - T_k) \right),
\]

13
we conclude from either of the two cases that
\[
P\left(x_\tau(k_* + 2) \leq h(k_*) \prod_{k=k_*}^{k_*+1} T_k(1 - T_k) + H(k_*)\left(1 - \prod_{k=k_*}^{k_*+1} T_k(1 - T_k)\right), \quad \tau = i_0, i_1, i_2 \right) \geq \left(\frac{\alpha a_*}{n}\right)^2.
\]

Continuing we obtain that for nodes \(i_3, \ldots, i_{n-1},\)
\[
P\left(x_\tau(k_* + n - 1) \leq h(k_*) \prod_{k=k_*}^{k_*+n-2} T_k(1 - T_k) + H(k_*)\left(1 - \prod_{k=k_*}^{k_*+n-2} T_k(1 - T_k)\right), \quad \tau = i_0, \ldots, i_{n-1} \right) \geq \left(\frac{\alpha a_*}{n}\right)^{n-1},
\]
which yields
\[
P\left(H(k_* + n - 1) \leq h(k_*) \prod_{k=k_*}^{k_*+n-2} T_k(1 - T_k) + H(k_*)\left(1 - \prod_{k=k_*}^{k_*+n-2} T_k(1 - T_k)\right)\right) \geq \left(\frac{\alpha a_*}{n}\right)^{n-1}.
\]

With \((21),\) we obtain
\[
P\left(\mathcal{H}(k_* + n - 1) \leq \left(1 - \prod_{k=k_*}^{k_*+n-2} T_k(1 - T_k)\right)\mathcal{H}(k_*)\right) \geq \left(\frac{\alpha a_*}{n}\right)^{n-1}. \tag{22}
\]

Since assumption \(\textbf{A2}\) guarantees \(\mathcal{H}(k + 1) \leq \mathcal{H}(k)\) for all \(k\) with probability one, \((22)\) leads to
\[
E\left(\mathcal{H}(k_* + n - 1)\right) \leq \left(1 - \left(\frac{\alpha a_*}{n}\right)^{n-1} \prod_{k=k_*}^{k_*+n-2} T_k(1 - T_k)\right)E\left(\mathcal{H}(k_*)\right). \tag{23}
\]

Note that \(k_*\) is chosen arbitrarily in the upper analysis. We conclude by induction that
\[
E\left(\mathcal{H}(k_* + (s + 1)(n - 1))\right) \leq \left(1 - \left(\frac{\alpha a_*}{n}\right)^{n-1} \prod_{k=k_*+s(n-1)}^{k_*+(s+1)(n-1)-1} T_k(1 - T_k)\right)E\left(\mathcal{H}(k_* + s(n - 1))\right)
\]
for all \(s = 0, 1, \ldots.\) Particularly, we choose \(k_* = K_0(n - 1) \geq k_0\) for some integer \(K_0 \geq 0,\) where \(k_0\) is the initial time, we obtain
\[
E\left(\mathcal{H}((s + 1)(n - 1))\right) \leq \sum_{t=K_0}^{s} \left(1 - \left(\frac{\alpha a_*}{n}\right)^{n-1} \prod_{k=t(n-1)}^{(t+1)(n-1)-1} T_k(1 - T_k)\right)E\left(\mathcal{H}(K_0(n - 1))\right),
\]
which implies
\[
E\left(\lim_{s \to \infty} \mathcal{H}(s(n - 1))\right) \leq \lim_{s \to \infty} E\left(\mathcal{H}(s(n - 1))\right) = 0 \tag{24}
\]
by Fatou’s Lemma and Lemma \(\text{A}\) as long as \(\sum_{k=0}^{\infty} \prod_{s=k(n-1)}^{(k+1)(n-1)-1} T_s(1 - T_s) = \infty.\) Therefore, observing that \(\mathcal{H}(k)\) is non-increasing, \((24)\) leads to
\[
P\left(\limsup_{k \to \infty} \mathcal{H}(k) = 0\right) = 1. \tag{25}
\]
The desired conclusion follows.

We see from Propositions 1 and 2 that it is easier to achieve agreement convergence with symmetric updates, which is consistent with the literature [43].

Again let us consider the case when \(T_k\) is monotone. The following lemma holds.

**Lemma 2** Let \(\{b_k\}_0^\infty\) be a sequence of real numbers with \(b_k \in [0, 1]\) for all \(k\).

(i) Suppose \(b_{k+1} \leq b_k\) for all \(k\). Then the following statements are equivalent.

\[
\begin{align*}
& a) \sum_{k=0}^\infty \prod_{s=k(n-1)}^{(k+1)(n-1)-1} b_s(1 - b_s) = \infty; \\
& b) \sum_{s=0}^\infty (b_s(1 - b_s))^{n-1} = \infty; \\
& c) \sum_{s=0}^\infty b_s^{n-1} = \infty.
\end{align*}
\]

(ii) Suppose \(b_{k+1} \geq b_k\) for all \(k\). Then the following statements are equivalent.

\[
\begin{align*}
& a) \sum_{k=0}^\infty \prod_{s=k(n-1)}^{(k+1)(n-1)-1} b_s(1 - b_s) = \infty; \\
& b) \sum_{s=0}^\infty (b_s(1 - b_s))^{n-1} = \infty; \\
& c) \sum_{s=0}^\infty (1 - b_s)^{n-1} = \infty.
\end{align*}
\]

**Proof.** We just prove (i). Case (ii) holds by a similar analysis. Note that, we have

\[
(1 - b_0)^{n-1}b_{(k+1)(n-1)}^{n-1} \leq \prod_{s=k(n-1)}^{(k+1)(n-1)-1} b_s(1 - b_s) \leq \prod_{s=k(n-1)}^{(k+1)(n-1)-1} b_s \leq b_{(k(n-1))}^{n-1},
\]

where without loss of generality we assume \(b_0 > 0\). Moreover, the monotonicity of \(\{b_k\}\) guarantees

\[
(n - 1) \sum_{k=0}^\infty b_{(k+1)(n-1)}^{n-1} \leq \sum_{k=0}^\infty b_s^{n-1} \leq (n - 1) \sum_{k=0}^\infty b_{(k(n-1))}^{n-1}.
\]

We see from (26) and (27) that statements a) and c) are equivalent.

On the other hand, observing that

\[
(1 - b_0)^{n-1} \sum_{s=0}^\infty b_s^{n-1} \leq \sum_{s=0}^\infty (b_s(1 - b_s))^{n-1} \leq \sum_{s=0}^\infty b_s^{n-1},
\]

also statements b) and c) are equivalent. The desired conclusion follows.

Combining Proposition 2 and Lemma 2 we obtain the following conclusion.

**Theorem 4** Suppose A1, A2 and A3 hold. Assume that either \(T_{k+1} \leq T_k\) or \(T_{k+1} \geq T_k\) for all \(k\). Then global agreement convergence is achieved a.s. if

\[
\sum_{k=0}^\infty \left((1 - T_k)T_k\right)^{n-1} = \infty.
\]

We see from Theorems 3 and 1 that the requirement for the sequence \(\{T_k\}_0^\infty\) to guarantee a.s. agreement convergence increases from \(\sum_{k=0}^\infty T_k(1 - T_k) = \infty\) to \(\sum_{k=0}^\infty ((1 - T_k)T_k)^{n-1} = \infty\) when the update transits from symmetric to asymmetric. Hence, these results quantify the cost of asymptotic updates versus the strength of attraction.
5 Attraction vs. Repulsion

In this section, we discuss the case when node repulsion is present in the model. Intuitively the main challenge here is whether the network reaches agreement convergence, or disagreement divergence, depending on which one can beat another one among node attraction and node repulsion. In the following, we study symmetric and asymmetric updates, respectively.

5.1 Symmetric Update

We first consider the case when the node updates are symmetric, as described in the following assumption.

A5. (Symmetric Update) The events $\mathcal{A}_{ij}(k) = \mathcal{A}_{ji}(k)$ and $\mathcal{R}_{ij}(k) = \mathcal{R}_{ji}(k)$ for all $(i, j)$ and $k$.

Let $\lambda_2^*$ and $\lambda_n^*$ be the second smallest and largest eigenvalues of $D - (A + A^T)$ with $D = \text{diag}(d_1 \ldots d_n)$, $d_i = \sum_{j=1}^{n}(a_{ij} + a_{ji})$, respectively. The main result on a.s. agreement convergence under symmetric update is stated as follows.

Proposition 3 Suppose A1 and A5 hold. Global agreement convergence is achieved a.s. if

$$\prod_{k=0}^{\infty} \left(1 - \frac{2}{n} I_k\right) = 0,$$

where

$$I_k = \begin{cases} 
(T_k(1 - T_k)\alpha - S_k(1 + S_k)\gamma) \lambda_2^*, & \text{if } T_k(1 - T_k) \geq S_k(1 + S_k); \\
(T_k(1 - T_k)\alpha - S_k(1 + S_k)\gamma) \lambda_n^*, & \text{if } T_k(1 - T_k) < S_k(1 + S_k).
\end{cases}$$

(28)

Proof. With assumption A5, the considered algorithm can be expressed as

$$x(k + 1) = \Psi(k)x(k),$$

(29)

where $\Psi(k)$ is a random matrix satisfying

$$P(\Psi(k) = \Psi_{ij}^+) = I - T_k(e_i - e_j)(e_i - e_j)^T) = \frac{\alpha}{n}(a_{ij} + a_{ji}), \quad i \neq j$$

corresponding to event $\mathcal{A}_{ij}(k)$, and

$$P(\Psi(k) = \Psi_{ij}^-) = I + S_k(e_i - e_j)(e_i - e_j)^T) = \frac{\gamma}{n}(a_{ij} + a_{ji}), \quad i \neq j.$$

(30)

corresponding to event $\mathcal{R}_{ij}(k)$.

Recall that $L(k) = \sum_{i=1}^{n} |x_i(k) - x_{\text{ave}}|^2$, where $x_{\text{ave}} = \sum_{i=1}^{n} x_i(k_0) / n$ is the initial average. It is crucial to notice that every possible sample of of the random matrix $\Psi(k)$ is symmetric and (generalized) stochastic since its row sum equals one, even though there are negative entries for the matrices $\Psi_{ij}^-$. Therefore, similar to [13], we have

$$E\left(L(k + 1) \mid x(k)\right) = (x(k) - x_{\text{ave}} 1)^T E(\Psi^2(k))(x(k) - x_{\text{ave}} 1).$$

(30)
Noticing (15) and
\[
(I + S_k(e_i - e_j)(e_i - e_j)^T)^2 = I + 2S_k(1 + S_k)(e_i - e_j)(e_i - e_j)^T
\]
we obtain
\[
E(\Psi^2(k)) = I - 2\left(T_k(1 - T_k)\alpha - S_k(1 + S_k)\gamma\right)\frac{1}{n}(D - (A + A^T)).
\] (31)

There are two cases.

(i). Suppose \(T_k(1 - T_k) \geq S_k(1 + S_k)\). Recalling that every eigenvalue \(\lambda_i^*\) of \(D - (A + A^T)\) is bounded by \(2n\), we have
\[
0 < 2\left(T_k(1 - T_k)\alpha - S_k(1 + S_k)\gamma\right)\frac{1}{n}\lambda_i^* \leq 2\left(T_k(1 - T_k)\alpha\right)\frac{1}{n}\lambda_i^* \leq 4T_k(1 - T_k) \leq 1
\]
for all \(\lambda_i^* \in \sigma(D - (A + A^T))\). Thus, all the eigenvalues of \(E(\Psi^2(k))\) are contained within the unit circle. This implies
\[
E\left(L(k+1) | x(k)\right) \leq (x(k) - x_{\text{ave}}1)^T E(\Psi^2(k)) (x(k) - x_{\text{ave}}1)
\]
\[
\leq \left(1 - 2\left(T_k(1 - T_k)\alpha - S_k(1 + S_k)\gamma\right)\frac{1}{n}\lambda_i^*\right) L(k)
\]
\[
= \left(1 - \frac{2}{n} I_k\right) L(k).
\]

(ii). Suppose \(T_k(1 - T_k) < S_k(1 + S_k)\). Then we have
\[
1 \leq \lambda_i\left(E(\Psi^2(k))\right) \leq 1 - 2\left(T_k(1 - T_k)\alpha - S_k(1 + S_k)\gamma\right)\frac{1}{n}\lambda_i^*
\]
for all eigenvalues of \(E(\Psi^2(k))\), which also yields
\[
E\left(L(k+1) | x(k)\right) \leq \left(1 - \frac{2}{n} I_k\right) L(k).
\]

Therefore, repeating the analysis in the proof of Proposition 1, we obtain
\[
E\left(\limsup_{k \to \infty} L(k)\right) \leq \limsup_{k \to \infty} E\left(L(k)\right) = 0,
\]
as long as \(\prod_{k=0}^{\infty} \left(1 - \frac{2}{n} I_k\right) = 0\). This immediately implies
\[
P\left(\lim_{k \to \infty} x_i(k) = x_{\text{ave}}\right) = 1,
\]
which completes the proof. \(\square\)

Next, we discuss the state disagreement under symmetric updates. The following conclusion holds on the state disagreement in expectation.
Proposition 4  Suppose A1 and A5 hold. Disagreement convergence is achieved in expectation, i.e., \( \lim_{k \to \infty} E(\mathcal{H}(k)) = \infty \), for almost all initial values if

\[
\prod_{k=0}^{\infty} \left(1 - \frac{2}{n} \hat{I}_k\right) = \infty,
\]

where

\[
\hat{I}_k = \begin{cases} 
(T_k(1 - T_k)\alpha - S_k(1 + S_k)\gamma)\lambda_n^*, & \text{if } T_k(1 - T_k) \geq S_k(1 + S_k); \\
(T_k(1 - T_k)\alpha - S_k(1 + S_k)\gamma)\lambda_k^*, & \text{if } T_k(1 - T_k) < S_k(1 + S_k).
\end{cases}
\]

Proof. By establishing the upper bound of the right-hand side of Eq. (30), we obtain

\[
E(L(k+1)|x(k)) \geq \left(1 - \frac{2}{n} \hat{I}_k\right)L(k)
\]

for all \( k \), which implies

\[
E(L(k+1)) \geq \left(1 - \frac{2}{n} \hat{I}_k\right)E(L(k)).
\]

This implies the desired conclusion straightforwardly. \( \square \)

For a.s. disagreement divergence, we present the following result.

Proposition 5  Suppose A1 and A5 hold. Disagreement divergence is achieved a.s. for almost all initial conditions if

(i) there exists a constant \( S^* > 0 \) such that \( S_k \leq S^* \) for all \( k \);

(ii) there exists a constant \( 0 < \varepsilon < 1/2 \) such that either \( T_k \in [0, 1/2 - \varepsilon] \) or \( T_k \in [1/2 + \varepsilon, 1] \) for all \( k \);

(iii) there exists \( 0 < \tau < 1 \) such that \( \limsup_{m \to \infty} \sum_{k=0}^{m} J_\tau(k) = O(m) \), where

\[
J_\tau(k) = \log \left[ (1 + 4\tau(S_k^2 + S_k))^{p_k} (2T_k - 1)^{2\alpha} \right]
\]

with \( p_k = \frac{2\hat{I}_k + \gamma(1 + 4\tau(S_k^2 + S_k))}{4(1-\tau)(S_k^2 + S_k)} \), and by definition \( b_k = O(c_k) \) means that \( \limsup_{k \to \infty} b(k)/c(k) < \infty \) is a nonzero constant.

Proof. We divide the proof into three steps.

Step 1. In this step, we show that with probability one and for almost all initial conditions, finite-time agreement convergence cannot be achieved. According to [39], we obtain

\[
P\left(\mathcal{H}(k+1) \geq (1 - 2T_k)\mathcal{H}(k)\right) = 1
\]

for all \( k \geq 0 \) if \( T_k \in [0, 1/2 - \varepsilon] \). Observing that \( 1 - 2T_k \geq 2\varepsilon > 0 \) we see that \( \mathcal{H}(k) > 0 \) for all \( k \) with probability one for all initial values satisfying \( \mathcal{H}(k_0) > 0 \). This holds also for the other case \( T_k \in [1/2 + \varepsilon, 1] \) based on a symmetric argument.
Suppose nodes $u$ and $v$ reach the maximum and minimum values at time $k$, respectively, i.e.,
$$x_u(k) = \max_{i \in V} x_i(k); \quad x_v(k) = \min_{i \in V} x_i(k).$$
Then we have
$$L(k) = \sum_{i=1}^n |x_i(k) - x_{\text{ave}}|^2 \geq |x_u(k) - x_{\text{ave}}|^2 + |x_v(k) - x_{\text{ave}}|^2 \geq \frac{1}{2}|x_u(k) - x_v(k)|^2 = \frac{1}{2}H^2(k),$$
which implies $L(k) > 0$ with probability one for almost all initial conditions.

Therefore, with probability one, we can introduce a sequence of random variables $\{\varpi_k\}_{0}^{\infty}$ satisfying
$$L(k+1) = \varpi_k L(k), \quad k \geq 0,$$
and we see from (33) that
$$\mathbb{E}(\varpi_k) = \mathbb{E}(L(k+1))/\mathbb{E}(L(k)) \geq 1 - \frac{2}{n} \hat{T}_k = Z_k. \quad (34)$$

Step 2. We establish a lower bound for $\mathbb{E}(\log \varpi_k)$ in this step.

Recall that $\Psi(k)$ is the random matrix introduced in (29). It is not hard to find that for every possible sample, $\Psi_{(ij)}^+$ or $\Psi_{(ij)}^-$ of $\Psi(k)$, it holds that
$$\min \left\{ |\lambda_i| : \lambda_i \in \sigma(\Psi_{(ij)}^+) \cup \sigma(\Psi_{(ij)}^-) \right\} \geq \min \left\{ |\lambda_i| : \lambda_i \in \sigma(\hat{V}_k) \right\} = 2T_k - 1, \quad (35)$$
where
$$V_k = \begin{pmatrix} 1 - T_k & T_k \\ T_k & 1 - T_k \end{pmatrix}. \quad (36)$$
Noticing that
$$L(k+1) = (x(k) - x_{\text{ave}})^T \Psi^2(k) (x(k) - x_{\text{ave}}) \geq \min_{\lambda_i \in \sigma(\Psi(k))} |\lambda_i|^2 L(k),$$
the definition of $\varpi_k$ and (35) yield
$$\mathbb{P}\left(\varpi_k \geq (2T_k - 1)^2\right) = \mathbb{P}\left(\log \varpi_k \geq \log(2T_k - 1)^2\right) = 1. \quad (37)$$
Similarly, observing that
$$\max \left\{ |\lambda_i| : \lambda_i \in \sigma(\Psi_{(ij)}^+) \cup \sigma(\Psi_{(ij)}^-) \right\} \leq \max \left\{ |\lambda_i| : \lambda_i \in \sigma(\hat{V}_k) \right\} = 2S_k + 1, \quad (38)$$
where
$$\hat{V}_k = \begin{pmatrix} 1 + S_k & -S_k \\ -S_k & 1 + S_k \end{pmatrix},$$
we obtain
$$\mathbb{P}\left(\varpi_k \leq (2S_k + 1)^2\right) = \mathbb{P}\left(\log \varpi_k \leq \log(2S_k + 1)^2\right) = 1. \quad (39)$$
Noticing (34) and that
\[ E(\varpi_k) = \int_{\varpi_k \leq 1} \varpi_k + \int_{\varpi_k > 1} \varpi_k \leq 1 + \int_{\varpi_k > 1} \varpi_k, \]
we obtain
\[ \int_{\varpi_k > 1} \varpi_k \geq E(\varpi_k) - 1 \geq Z_k - 1. \]

Take $0 < \tau < 1$ a constant. Based on the definition of the desired algorithm, we see that
\[ P(\varpi_k > 1) \leq P(\mathcal{R}_{ij}(k) \text{ happens for some node pair } (i, j)) = \gamma. \]

Now we conclude that
\[ Z_k - 1 \leq \int_{\varpi_k > 1} \varpi_k \leq \hat{p}_k (2S_k + 1)^2 + (1 - \tau + \tau(2S_k + 1)^2)(\gamma - \hat{p}_k), \tag{40} \]
where by definition
\[ \hat{p}_k = P(1 - \tau + \tau(2S_k + 1)^2 \leq \varpi_k \leq (2S_k + 1)^2). \]

After some simple algebra we see from (40) that
\[ \hat{p}_k \geq \frac{Z_k - 1 - \gamma(1 - \tau + \tau(2S_k + 1)^2)}{4(1 - \tau)(S_k^2 + S_k)} = -\frac{2\tilde{I}_k + \gamma(1 + 4\tau(S_k^2 + S_k))}{4(1 - \tau)(S_k^2 + S_k)} \equiv p_k. \tag{41} \]

Combining (37), (39) and (41), we eventually arrive at the following lower bound of $E \log \varpi_k$:
\[
E \log \varpi_k \geq \hat{p}_k \log \left(1 - \tau + \tau(2S_k + 1)^2\right) + \alpha \log(2T_k - 1)^2
\geq \log \left[ (1 + 4\tau(S_k^2 + S_k))^{\hat{p}_k} (2T_k - 1)^{2\alpha} \right]
\geq J_\tau(k). \tag{42}
\]

Step 3. In this step, we complete the final piece of the proof by a contradiction argument. Suppose there exist two constants $M_0 \geq 0$ and $0 < p < 1$ such that
\[ P\left(\limsup_{k \to \infty} \mathcal{H}(k) \leq M_0\right) = p. \tag{43} \]

Noticing that
\[
L(k) = \sum_{i=1}^{n} |x_i(k) - x_{\text{ave}}|^2 \leq n\mathcal{H}^2(k),
\]
we further conclude
\[ P\left(\limsup_{k \to \infty} L(k) \leq nM_0^2\right) \geq p, \]
\[ \text{Combining (37), (39) and (41), we eventually arrive at the following lower bound of } E \log \varpi_k: \]
\[ E \log \varpi_k \geq \hat{p}_k \log \left(1 - \tau + \tau(2S_k + 1)^2\right) + \alpha \log(2T_k - 1)^2 \]
\[ \geq \log \left[ (1 + 4\tau(S_k^2 + S_k))^{\hat{p}_k} (2T_k - 1)^{2\alpha} \right] \]
\[ \geq J_\tau(k). \]
which yields
\[ P\left( \lim sup_{m \to \infty} \log L(m + 1) = \sum_{k=0}^{m} \log \varpi_k \leq \log (nM_0^2) \right) \geq p. \]

This leads to
\[ P\left( \lim_{m \to \infty} \frac{\sum_{k=0}^{m} \log \varpi_k}{m} \leq 0 \right) \geq p. \]  \hspace{1cm} (44)

On the other hand, noting that the node updates are independent of time and node states, and that \( V(\log \varpi_k) \) is bounded according to (37) and (39), the Strong Law of Large Numbers and (42) suggest that
\[ P\left( \lim_{m \to \infty} \frac{1}{m} \sum_{k=0}^{m} (\log \varpi_k - J_\tau(k)) \geq 0 \right) \geq P\left( \lim_{m \to \infty} \frac{1}{m} \sum_{k=0}^{m} (\log \varpi_k - \mathbb{E} \log \varpi_k) = 0 \right) = 1, \]
which contradicts (44) if \( \lim sup_{m \to \infty} \sum_{k=0}^{m} J_\tau(k) = O(m) \).

The desired conclusion thus follows and this completes the proof. \( \square \)

We conclude this subsection by the following conclusion under the condition when \( T_k \) and \( S_k \) are time-invariant, which follows straightforwardly from Propositions 3, 4 and 5.

**Theorem 5** Suppose A1 and A5 hold. Let \( T_* \in [0,1] \) and \( S_* > 0 \) be two given constants. Assume that \( T_k \equiv T_* \) and \( S_k \equiv S_* \). Then
\[ D_0 = S_* (1 + S_*) \gamma - T_* (1 - T_*) \alpha \]
is a critical convergence measure regarding the state convergence of the considered network. To be precise, we have

(i) Global agreement convergence is achieved a.s. if \( D_0 < 0 \);

(ii) Disagreement divergence is achieved in expectation for almost all initial values if \( D_0 > 0 \);

(iii) State oscillation is achieved in expectation, i.e., \( \mathbb{E}(L(k)) = L(k_0) \) for all \( k \geq k_0 \) if \( D_0 = 0 \);

(iv) Disagreement divergence is achieved a.s. for almost all initial conditions if \( T_* \neq 1/2 \) and \( D_0 \) is sufficiently large, i.e., there exists \( 0 < \tau < 1 \) such that
\[ (1 + 4\tau (S_*^2 + S_*))^{p^*} (2T_* - 1)^{2\alpha} > 1, \]
where
\[ p^* = \frac{2D_0\lambda^2 - n\gamma(1 + 4\tau (S_*^2 + S_*))}{4n(1-\tau)(S_*^2 + S_*)}. \]

**Remark 1** It is surprising that the convergence measure \( D_0 \) in Theorem 5 does not rely on the network topology. This is to say, if all the nodes may misbehave with equal probability as the proposed algorithm, then there is no particular topology which can be viewed as “better” than others in terms of agreement convergence.
5.2 Asymmetric Update

In this subsection, we discuss asymmetric node updates. We introduce the following assumption.

A6. (Asymmetric Update) Both \( \mathcal{A}_{ij}(k) \cap \mathcal{A}_{ji}(k) \) and \( \mathcal{R}_{ij}(k) \cap \mathcal{R}_{ji}(k) \) are trivial events for all \((i, j)\) and \(k\).

The main result on a.s. agreement convergence under asymmetric update is as follows.

**Proposition 6** Suppose A1 and A6 hold. Global agreement convergence is achieved a.s. if there exists \( S^* > 0 \) such that

\[
\prod_{k=0}^{\infty} \left[ 1 - \left( \frac{\alpha a_*}{n} \right)^{n-1} \hat{T}_k + \left( 1 - (1 - \gamma)^{n-1} \right) \left( \hat{S}_k - 1 \right) \right] = 0, \tag{45}
\]

where

\[
\hat{T}_k = \prod_{m=k(n-1)}^{(k+1)(n-1)-1} T_m(1 - T_m); \quad \hat{S}_k = \prod_{m=k(n-1)}^{(k+1)(n-1)-1} (S_m + 1).
\]

**Proof.** Following from the proof of Proposition 2, we have

\[
P \left( \mathcal{H}(k_\star + n - 1) \leq \left( 1 - \prod_{k=k_\star}^{k_\star + n - 2} T_k(1 - T_k) \right) \mathcal{H}(k_\star) \right) \geq \left( \frac{\alpha a_*}{n} \right)^{n-1} \tag{46}
\]

for all \( k_\star \geq 0 \).

On the other hand, the definition of the randomized algorithm leads to

\[
P \left( \mathcal{H}(k_\star + n - 1) \leq \left( \prod_{k=k_\star}^{k_\star + n - 2} (S_k + 1) \right) \mathcal{H}(k_\star) \right) = 1 \tag{47}
\]

and

\[
P \left( \mathcal{H}(k_\star + n - 1) > \mathcal{H}(k_\star) \right) \leq 1 - (1 - \gamma)^{n-1} \tag{48}
\]

since \( \mathcal{H}(k_\star + n - 1) > \mathcal{H}(k_\star) \) implies that repulsion happens at least one time during \([k_\star, k_\star + n - 1]\).

We conclude from (46) and (47) that

\[
E(\mathcal{H}(k_\star + n - 1)) \leq \left[ \left( 1 - \prod_{k=k_\star}^{k_\star + n - 2} T_k(1 - T_k) \right) \left( \frac{\alpha a_*}{n} \right)^{n-1} + (1 - \gamma)^{n-1} - \left( \frac{\alpha a_*}{n} \right)^{n-1} \right. \]

\[
\left. + \left( 1 - (1 - \gamma)^{n-1} \right) \prod_{k=k_\star}^{k_\star + n - 2} (S_k + 1) \right] E(\mathcal{H}(k_\star))
\]

\[
= \left[ 1 - \left( \frac{\alpha a_*}{n} \right)^{n-1} \prod_{k=k_\star}^{k_\star + n - 2} T_k(1 - T_k) \right. \]

\[
\left. + \left( 1 - (1 - \gamma)^{n-1} \right) \prod_{k=k_\star}^{k_\star + n - 2} (S_k + 1) - 1 \right] E(\mathcal{H}(k_\star))
\]
for all $k_0 > 0$. This implies
\[
\mathbb{E}\left( \lim_{s \to \infty} \mathcal{H}(s(n - 1)) \right) \leq \lim_{s \to \infty} \mathbb{E}\left( \mathcal{H}(s(n - 1)) \right) = 0
\] (49)
if (45) holds, and thus
\[
\mathbb{P}\left( \lim_{k \to \infty} \mathcal{H}(k(n - 1)) = 0 \right) = 1.
\] (50)

Since there exists $S^* > 0$ a such that $S_k \leq S^*$ for all $k$, we see from (47) and (50) that
\[
\mathbb{P}\left( \lim_{k \to \infty} \mathcal{H}(k) = 0 \right) = 1.
\]
The desired conclusion follows. \(\Box\)

Next, we study a.s. disagreement divergence. The following conclusion holds.

**Proposition 7** Suppose A1 and A6 hold. Disagreement divergence is achieved a.s. for almost all initial values if

(i) there exist two constants $S^* > 0$ and $0 < T^* < 1$ such that $S_k \leq S^*$ and $T_k \leq T^*$ for all $k$.

(ii) there exists an integer $Z \geq 0$ such that $\sum_{k=0}^{m} J_Z(k) = O(m)$, where
\[
J_Z(k) = \left( \frac{\gamma a_s}{n} \right)^{Z+1} \log \left( \frac{1}{n-1} \prod_{c=k(Z+1)}^{(k+1)(Z+1)-1} (1 + S_c) \right) + (1 - (1 - \alpha)^{Z+1}) \log \prod_{c=k(Z+1)}^{(k+1)(Z+1)-1} (1 - T_c).
\]

Proof. Suppose node pair $(i, j)$ is selected at time $k$. According to the definition of the considered randomized algorithm, we obtain
\[
|x_i(k + 1) - x_j(k + 1)| = \begin{cases} |x_i(k) - x_j(k)|, & \text{if } \mathcal{M}_{ij}(k) \text{ happens;} \\ (1 - T_k)|x_i(k) - x_j(k)|, & \text{if } \mathcal{A}_{ij}(k) \text{ happens;} \\ (1 + S_k)|x_i(k) - x_j(k)|, & \text{if } \mathcal{R}_{ij}(k) \text{ happens.}
\end{cases}
\] (51)

Therefore, with assumption A6, we obtain
\[
\mathbb{P}\left( \mathcal{H}(k + 1) \geq (1 - T_k)\mathcal{H}(k) \right) \geq \mathbb{P}\left( \mathcal{H}(k + 1) \geq (1 - T^*)\mathcal{H}(k) \right) = 1
\]
for all $k \geq 0$. This implies for all initial values satisfying $\mathcal{H}(k_0) > 0$, agreement convergence is achieved only in infinite time with probability one. As a result, we can well define a sequence of random variable, $\{\tilde{x}_k\}_{0}^{\infty}$, such that
\[
\mathcal{H}(k + 1) = \tilde{x}_k\mathcal{H}(k), \quad k \geq 0.
\]
Now with (51), it is straightforward to conclude that
\[
\mathbb{P}\left( \tilde{x}_k \geq 1 - T_k \right) = 1
\] (52)
Remark 2

It is unclear from Theorems 5 and 6 if symmetric or asymmetric updates are better guiding the network states to agreement or disagreement. In order to answer this question, more accurate estimates of the state evolution are needed. We guess the answer will highly depend on the network topology.
5.3 Numerical Example

We present a numerical example in order to illustrate the critical measure established in Theorem 5. Consider four nodes 1, ..., 4. The node meeting probability matrix is given by

\[
A = \begin{bmatrix}
0 & 1/2 & 0 & 1/2 \\
1/2 & 0 & 1/4 & 1/4 \\
1/3 & 0 & 0 & 2/3 \\
0 & 1/3 & 2/3 & 0
\end{bmatrix}.
\]

The underlying graph \( G_0 \) is shown in the Fig. 1. The initial values are taken as \( x_i(0) = i, i = 1, \ldots, 4 \). We take \( \alpha = \beta = \gamma = 1/3 \) and let \( T_k \equiv T_* \) and \( S_k \equiv S_* \).

Take \( T_* = 1/4 \) and \( S_* = (\sqrt{7} - 2)/4, (\sqrt{7} - 2)/4 - 0.05, (\sqrt{7} - 2)/4 + 0.05 \), respectively. The corresponding values of \( D_0 = S_*(1 + S_*)\gamma - T_*(1 - T_*)\alpha \) are then given by 0, -0.0212, and 0.0229. We run the considered randomized algorithm for \( 10^5 \) times, and then take the average value of the consensus measure \( L(k) = \sum_{i=1}^{4} (x_i(k) - x_{ave})^2 \) as the empirical estimate of the expected value of \( L(k) \). The transition of \( \mathbb{E}(L(k)) \) for these three cases of \( D_0 \) is shown in Fig. 2. The numerical result is consistent with the conclusion in Theorem 5.

6 Conclusions

This paper proposed a model for investigating node misbehavior in distributed information processing over random networks. At each instance, two nodes were selected for a meeting with a given probability. When nodes meet, there were three events for the node update: attraction, neglect, or repulsion. Attraction event follows the standard averaging algorithm targeting a consensus; neglect event means the selected node will stick to its current state; repulsion event...
represents the case when nodes are against the consensus convergence. Each node was assumed to follow one of these three update rules at random. Both symmetric and asymmetric node updates were studied. After obtaining two general impossibility theorems, a series of necessary and/or sufficient conditions were established for the network to reach a.s. agreement convergence, or a.s. disagreement divergence. For the symmetric update model, we established a critical convergence measure stating that convergence transits from agreement to disagreement whenever this measure goes from negative to positive. The proposed algorithm may serve a uniform model for characterizing node misbehavior in communication network, large-scale control system, or social networks. To the best of our knowledge, the obtained results for the first time in the literature gave a clear description on the possible disagreement divergence for distributed averaging due to node misbehavior. More challenges lie in the optimal policy for the nodes to take bad action from a tradeoff between the risk of being discovered and the result it generates, and the case when bad action only takes place for some particular neighboring relations.
