Abstract

We employed a random mutagenesis approach to identify novel monogenic determinants of type 2 diabetes. Here we show that haplo-insufficiency of the histone methyltransferase myeloid-lineage leukemia (*Mll2*/Wbp7) gene causes type 2 diabetes in the mouse. We have shown that mice heterozygous for two separate mutations in the SET domain of *Mll2* or heterozygous *Mll2* knockout mice were hyperglycaemic, hyperinsulinaemic and developed non-alcoholic fatty liver disease. Consistent with previous *Mll2* knockout studies, mice homozygous for either ENU mutation (or compound heterozygotes) died during embryonic development at 9.5–14.5 days post coitum. Heterozygous deletion of *Mll2* induced in the adult mouse results in a normal phenotype suggesting that changes in chromatin methylation during development result in the adult phenotype. *Mll2* has been shown to regulate a small subset of genes, a number of which *Neurod1*, Enpp1, Slc27a2, and *Pldc1* are downregulated in adult mutant mice. Our results demonstrate that histone H3K4 methyltransferase *Mll2* is a component of the genetic regulation necessary for glucose homeostasis, resulting in a specific disease pattern linking chromatin modification with changes and progression of type 2 diabetes, providing a basis for its further understanding at the molecular level.

Introduction

Type 2 diabetes is a major and increasing health problem worldwide. It is estimated that the global average prevalence of diabetes worldwide is 10% (WHO World Health Statistics 2012 report). Type 2 diabetes is generally a later onset form of diabetes and is characterized by defects in insulin action and secretion. In addition to environmental factors, such as obesity, leading to increased diabetes risk it has been clearly demonstrated that there is a complex genetic component. In recent years there has been great success using genome wide association studies to identify, in humans, candidate loci containing genes conferring risk for type 2 diabetes or sub-diabetic traits, although in the context of these studies these are small effect alleles [1–14] [reviewed [15,16]].

To maintain or initiate gene expression, the local chromatin structure must be in an active state to allow access to transcription factor complexes. Histone molecules have a range of acetylation or methylation modifications that are associated with active or inactive chromatin [reviewed in [17,18]]. Furthermore, transcriptional activity is often associated with trimethylation at the fourth lysine residue of histone H3 (H3K4) at active promoter regions [19,20]. Intrauterine growth retardation (IUGR) induced in rats causes the *Pdx1* locus in pancreatic β-cells to undergo changes in histone methylation and acetylation that results in progressive transcriptional silencing and development of type 2 diabetes [21]. Similarly, adult *Gata4* gene transcription is reduced in skeletal muscle in an IUGR rat model due to changes in chromatin methylation and DNA methylation [22]. Finally, *Huf4x*, a gene linked to diabetes, is progressively epigenetically silenced in rat beta cells due to poor maternal diet and aging [23]. In *in vitro* studies of human monocytes under normal or high glucose indicated changes in expression of candidate genes linked to glucose dependent changes in histone methylation [24]. These studies provide limited evidence that chromatin remodeling is involved in glucose homeostasis.

Phenotype-driven N-ethyl-N-nitrosourea (ENU) mutagenesis screens have been shown to be an effective tool for the identification of novel murine models of human disease [25,26].
including new mouse models of type 2 diabetes [27,28]. Using this approach, we identified a novel mouse model of type 2 diabetes that also exhibits features of non-alcoholic fatty liver disease (NAFLD). By mapping and sequencing we have identified a mutation in a histone 3 lysine 4 (H3K4) methyltransferase, myeloid-lineage leukemia 2 (Mll2/Wbp7). We also identified additional alleles in the mouse and confirmed the functional link between this gene and type 2 diabetes phenotypes [29]. Finally, we describe evidence that Mll2 contributes to glucose homeostasis through altered gene regulation established during development.

**Materials and Methods**

**Animal Husbandry**

Mice were kept in accordance with UK Home Office Welfare guidelines and project license restrictions and in addition the study was approved by the local Ethical Review Panel committee. Mll2FC and Mll2KO/+ mice were a kind gift from Professor Frances Stewart (Dresden University of technology, Germany). B6.Cg-Tg(UBC-cre/ERT2)1Ejb/J a Tamoxifen-inducible cre was obtained from the Jackson Laboratory (Bar harbor, ME). All mouse lines were maintained by on a C3H/HeH background by Backcrossing. Mice were sacrificed by either cervical dislocation or exsanguination under general anesthesia.

**Tamoxifen Knockout Mll2FC**

Tamoxifen was resuspended in Corn Oil +2% Ethanol at a concentration of 30 mg/ml. Mice were dosed at 8 weeks of age via oral gavage with 200 mg/kg Tamoxifen or vehicle control once a day for 5 days.

**Intraperitoneal Glucose Tolerance test and biochemistry**

Mice were tested using the EMPreSS IPGTT [http://empress.har.mrc.ac.uk]. In insulin Tolerance tests (ITT), mice were fasted for 4 hours and a T0 blood sample taken and an Intraperitoneal injection of 2IU/Kg of insulin administered. Subsequent blood samples were taken at 15, 30, 45 and 60 minutes and blood glucose determined using a GM9 glucose analyser (Plasma, Analog, UK) or glucocontrol strips (Whole blood). Plasma insulin was measured using a Mercodia ultra-sensitive mouse ELISA kit according to the manufacturer’s instructions. The plasma concentrations of glucose, triglycerides, total cholesterol, HDL cholesterol and LDL cholesterol were measured on an AU4000 (Olympus UK).

**Isolated Islets**

Mice were killed by cervical dislocation, the pancreas removed, and islets isolated by liberase digestion and handpicking [30]. Cells were maintained in this medium at 37°C in a humidified atmosphere at 5% CO2 in air, and used 24 hours after the isolation. Insulin secretion was measured during 1-hour static incubations in Krebs-Ringer Buffer as described previously [30].

**DNA archive screen**

The Harwell DNA archive was screened utilising High-resolution DNA melting analysis performed on the Idaho Technology LightScanner as described previously [30].

**Genotyping and sequencing**

Genomic DNA was extracted from either mouse tail or ear using a Qiagen DNeasy tissue kit (Qiagen, UK) according to the manufacturer’s instructions. The DNA of the founder F1 mouse was sequenced within coding regions of 26 of the 27 genes within the mapped interval, not including the Gapdh gene that was also sequenced apart from 150 bp of repeat sequence (Table S1). Genotyping of the two Mll2 ENU mutations was performed by pyrosequencing. The Mll2 KO mice were genotyped using a generic Neo PCR assay.

**Histology and Islet immunohistochemistry**

The pancreas and liver from each mouse was fixed in neutral buffered formaldehyde and mounted in wax longitudinally. Serial sections were cut and stained with Hematoxylin and Eosin (H&E). A rabbit ABC staining system (Santa Cruz Biotechnology) was used according to manufacturer’s instructions. The following primary antibodies were used: rabbit anti-human glucagon (1:40; AbD Serotec), rabbit anti-somatostatin (2 μg/ml; Chemicon International). Sections were counterstained with Gill’s formulation no. 2 hematoxylin. H-E stained sections from each mouse were photographed completely, and islet area calculated using Adobe Photoshop to measure islet area and total pancreas section area in each image. Liver histology was assessed by an expert histopathologist (RG) for steatosis and steatohepatitis using the NIDDK NASH Clinical Research Network histological classification [31].

**Embryo Dissection**

Mice heterozygous for both ENU mutations were crossed to mice heterozygous for the same mutation or the Mll2 KO allele. Embryo dissections were carried out between 8.5 and 14.5 days post coitum (dpc) and the embryonic phenotype was visually analyzed.

**Quantitative RT-PCR**

RNA was extracted from snap frozen tissues with RNeasy Mini Prep (Qiagen) kits according to the manufactures instructions. cDNA generated by Superscript II enzyme (Invitrogen, UK) was analysed by quantitative RT-PCR using the TaqMan system based on real-time detection of accumulated fluorescence (ABI Prism 7700, Perkin-Elmer Inc., USA). Gene expression was normalised relative to the expression of glyceraldehyde-3-phosphate dehydrogenase (Gapdh). Taqman Probes with FAM tags were purchased from Applied Biosystems (ABI, USA). Samples were tested in triplicate and results expressed relative to Gapdh.

**Site-directed mutagenesis and Protein expression**

The SET domain from MLL1 comprising the last 178 amino acids (with 86% sequence identity to the MLL2 SET domain sequence, Figure S1) was expressed as a glutathione S-transferase (GST) fusion protein from the expression vector pGEX-2T (GE Healthcare) in Escherichia coli Rosetta (DE3) (Novagen). (Several Mll2 constructs failed to express under identical conditions.) Expression was induced with 0.2 mM isopropyl- D-thiogalacto- pyranoside for 24 hours at 20°C. The enzyme was purified over a glutathione-Sepharose 4B column (GE Healthcare). After dialysis against a buffer containing 50 mM Tris/HCl, pH 8.5, 100 mM NaCl, 1 mM dithiothreitol, and 10% glycerol the enzyme was stored at −80°C. The enzyme concentration was determined using the FluoroProfile® Protein Quantification kit (Sigma-Aldrich). The expression and purification procedure of the M388H-K mutant of MLL1 was identical to the wild-type enzyme.

**In vitro methylation assays**

The biotinylated peptide substrates comprising the first 21 N-terminal amino acids of human histone H3 were immobilized on streptavidin-coated 96 well microtiter plates (Sigma) by incubating
50 μL of 5 μg/mL peptide in PBS per well for 1 h at room temperature. After washing three times with water, each well was incubated with 200 μL of 3% bovine serum albumin in PBS for 2 h at room temperature. Following a washing step with PBS (3 times) each well was incubated with 50 μL of methylation reaction mixture (1 μM methyltransferase, 1 mM S-adenosyl-L-methionine (Fluka; purity ≥80%), stored in 10 mM H2SO4 at −20°C), 50 mM Tris-Cl, pH 8.5, 100 mM NaCl, 2 mM dithiothreitol) or the control reaction (1 mM S-adenosyl-L-methionine, 50 mM Tris-Cl, pH 8.5, 100 mM NaCl, 2 mM dithiothreitol). The plates were incubated for the indicated time intervals at 30°C and subsequently washed three times with PBS. To detect the respective modifications each well was incubated with 50 μL of anti-H3K4Me1, anti-H3K4Me2, or anti-H3K4Me3 antibody (diluted 1:250 in 3% bovine serum albumin, PBS) for 45 min at room temperature. The wells were then washed twice with PBST (PBS-0.5% Tween-20)/500 mM NaCl followed by washing twice with PBST and 3 times with PBS. The wells were then incubated with 50 μL of the secondary anti-rabbit IgG horseradish peroxidase conjugate (Sigma-Aldrich) (diluted 1:5000 in 3% bovine serum albumin, PBS) for 45 min at room temperature. After a washing step with PBST (three times) and with water (three times) each well was incubated with 100 μL of TMB Microwell Horseradish Peroxidase Substrate (KPL) for 10 min. 50 μL of 1M H2PO4 were added and the absorbance measured at 450 nm on a Spectra-MaxPlus reader (Molecular Devices). For each peptide substrate, the values obtained without enzyme were defined as background and subtracted from those obtained for the enzymatic methylation. The synthetic peptides used for the methylation assays correspond to amino acids 1–21 of human histone H3 with lysine4 methyltransferase domain using the Harwell ENU DNA/Sperm mutagenesis screen, where BALB/c male mice were treated with ENU and then crossed to female C3H/HeH mice as previously described [25]. The Mll2 line was identified as an individual G1 (BALB/c x C3H/HeH) male mouse (called GENA263) with elevated free-fed blood glucose [32]. Inheritance of the phenotype was confirmed by generating offspring by backcrossing to C3H/HeH for two generations, phenotyped by IPGTT, data not shown).

Identification of mutations in Mll2

To identify the underlying mutation, mutant mice were backcrossed to C3H/HeH for two generations, phenotyped by an IPGTT and placed into affected or unaffected groups where affected mice had glucose levels 2 standard deviations (SD) or more above the population mean (data not shown). A genome-wide scan was performed on DNA from these crosses and a region of BALB/c DNA identified on chromosome 7 between D7Mit267 and D7Mit25 that was associated with the impaired glucose tolerance phenotype. Successive backcrossing to C3H/HeH mice and genotyping of DNA recombination events narrowed this candidate region to a 350 kilo-base-pair (kb) region of chromosome 7. All the coding regions of 26 of the 27 genes within the region, not including spermatogonic Gapdh, (Table S1) were sequenced in the founder F1 DNA to identify homozygous base pairs. An ENU induced thymine to adenine (T7942A, transcript Wbp7-001, ENSMUST00000109154, NCBIM37) transversion was identified in exon 36 of the gene encoding myeloid-lineage leukemia 2 (Mll2/Wbp7) (NM_029274, NP_083550). The Mll2T7942A mutation causes a methionine to lysine amino acid change at residue 2628 (M2628K) within the highly conserved SET Su(var)3-9, enhancer(zeste) methyltransferase domain (Figure 1A) [33]. As the crystal structure of the homologous MLL1 SET domain has been elucidated it is possible to map the Mll2M2628K mutation onto this structure where it corresponds to residue MLL1K3524 and occupies a position in the lysine binding groove (Figure 1B) [34].

Identification of a mouse hyperglycaemia model

A random phenotype driven N-ethyl-N-nitrosourea (ENU) mutagenesis screen, where BALB/c male mice were treated with ENU and then crossed to female C3H/HeH mice was performed as previously described [25]. The Mll2 line was identified as an individual G1 (BALB/c x C3H/HeH) male mouse (called GENA263) with elevated free-fed blood glucose [32]. Inheritance of the phenotype was confirmed by generating offspring by backcrossing to C3H/HeH mice and measuring glucose tolerance at 12 weeks of age in an intraperitoneal glucose tolerance test (IPGTT, data not shown).

Results

Identification of mutations in Mll2

To identify the underlying mutation, mutant mice were backcrossed to C3H/HeH for two generations, phenotyped by an IPGTT and placed into affected or unaffected groups where affected mice had glucose levels 2 standard deviations (SD) or more above the population mean (data not shown). A genome-wide scan was performed on DNA from these crosses and a region of BALB/c DNA identified on chromosome 7 between D7Mit267 and D7Mit25 that was associated with the impaired glucose tolerance phenotype. Successive backcrossing to C3H/HeH mice and genotyping of DNA recombination events narrowed this candidate region to a 350 kilo-base-pair (kb) region of chromosome 7. All the coding regions of 26 of the 27 genes within the region, not including spermatogonic Gapdh, (Table S1) were sequenced in the founder F1 DNA to identify homozygous base pairs. An ENU induced thymine to adenine (T7942A, transcript Wbp7-001, ENSMUST00000109154, NCBIM37) transversion was identified in exon 36 of the gene encoding myeloid-lineage leukemia 2 (Mll2/Wbp7) (NM_029274, NP_083550). The Mll2T7942A mutation causes a methionine to lysine amino acid change at residue 2628 (M2628K) within the highly conserved SET Su(var)3-9, enhancer(zeste) methyltransferase domain (Figure 1A) [33]. As the crystal structure of the homologous MLL1 SET domain has been elucidated it is possible to map the Mll2M2628K mutation onto this structure where it corresponds to residue MLL1K3524 and occupies a position in the lysine binding groove (Figure 1B) [34].

To probe whether the observed phenotypes can be ascribed to an impairment of the methyltransferase function of the SET domain, a M3884K mutant MLL1 (the SET domains are highly conserved between the two genes, Figure S1) equivalent to M2628K in MLL2 (that in our hands could not be expressed) was tested in in vitro assays (Figure S2). The SET domain of wild-type and mutant MLL1 was thus expressed in E.coli, purified by affinity chromatography and histone mono-, di- and trimethylation was quantified by ELISA (Figure S3) [35]. The MLL1M3524K protein had significantly reduced methyltransferase activity compared to the MLL1 wild type, demonstrating this residue was indeed required for methyltransferase activity (Figure S2).

In order to confirm that mutation of Mll2 underlies the phenotypes we sought to identify additional mutant alleles of Mll2. Firstly, we screened for mutations within the Mll2 SET methyltransferase domain using the Harwell ENU DNA/Sperm archive [29,36]. An additional thymine to adenine (T7942A) transversion was identified and results in a phenylalanine to isoleucine amino acid change at residue 2648 (NP_083550, F2648I). The Mll2F2648I mutation maps to MLL1P19001 and is located in an α5 helix of the SET-C domain in a region of the protein important for interaction with the co-factor Adduc1 (Figure 1C) [34]. Secondly, a global knockout of the Mll2 allele was kindly provided by Professor Frances Stewart (Dresden University of Technology, Germany) for additional analysis [33].

Statistical Analysis

The calculations and statistical analyses (2-sample t-test were conducted using Excel and Prism). Unless otherwise specified data is expressed as mean ± SD. Differences with a p<0.05 were defined as significant.

Homozogous Mll2 mutants are embryonic lethal

Homozogous Mll2 knockout mice die of widespread apoptosis prior to 11.5 dpc and we therefore tested the functionality of our 2 ENU mutations in homozygous individuals [33]. No homozygous pups were identified from these matings (Table 1) showing that homozygosity of both the ENU alleles is non-viable. To determine the time and cause of lethality, we dissected pregnant females at 8.5, 12.5 and 14.5 dpc and genotyped the embryos for the Mll2M2628K/M2628K allele. The percentage of homozygous individuals was lower than expected at both 12.5 and 14.5 dpc (Table 1). This suggested that the majority of Mll2M2628K/M2628K embryos were dying between 8.5 and 11.5 dpc. The most common defects identified in the embryos were evident as early as 10.5 dpc and up to 12.5 dpc and included pericardial effusion, abnormal heart looping, exencephaly and various head abnormalities and anterior truncation defects (Figure 2A–F). The observed heart and/or circulation defects are the most likely cause of non-viability in Mll2M2628K/M2628K embryos.

As the homozogous lethal phenotype of Mll2M2628K is not identical to the published phenotype of Mll2 knockout mice we investigated the effect of combining the two mutations. We set up crosses between Mll2M2628K/+ and heterozygous Mll2M2628K+/− knock-
out mice to create trans-heterozygote Mll2M2628K/+ animals. No trans-heterozygous pups were born (Table 2). Dissection of pregnant females at 8.5, 12.5 and 14.5 dpc and determined that the embryos were dying between 8.5 and 12.5 dpc. The defects observed in these trans-heterozygotes were similar to Mll2M2628K/M2628K embryos and included exencephaly, oedema and pericardial effusion (Figure 2G–I). Thus the two mutations fail to complement.

Mutation of Mll2 leads to adult impaired glucose tolerance and insulin resistance

Having established the underlying genetics, both ENU derived mutant alleles and global heterozygous knockout Mll2 mice were further characterised for glucose tolerance and insulin sensitivity. Intraperitoneal Glucose Tolerance Tests (IPGTT) were carried out at 12 weeks of age (Figure 3A). In all 3 lines, in comparison to wild-type littermates, we observed significantly elevated plasma glucose at fasting and at all time points during the IPGTT, with levels failing to return to normal at 120 minutes. In order to further investigate the underlying physiological defect in the Mll2 mutants we measured plasma glucose and insulin at 0, 10, 20 and 30 minutes after an intraperitoneal (IP) injection of glucose at 16 weeks of age (Figure 3B and C). The fasting plasma insulin concentrations of all 3 lines were significantly higher than the wild-type littermates. However unlike wild-type littermates Mll2 mutant or heterozygous knockout mice showed a marked decrease in insulin secretion in response to the glucose challenge, suggesting that the impaired glucose tolerance observed is due in part due to an insulin secretory defect.

To test whether the mice are also insulin resistant Insulin Tolerance Tests (ITT) were carried out on new cohorts of mice at 12 weeks of age. An insulin load of 2IU/Kg was administered IP after a four hour fast and plasma glucose concentrations measured at 15, 30, 45 and 60 minutes post insulin injection. Results were normalised for differences in fasted glucose levels by expressing glucose concentrations as a percentage of the T0 concentration. There was a significant reduction in the fall of glucose levels in Mll2 mutant and knockout mice in response to insulin (Figure 3D).

To investigate the failure of Mll2 mutant mice to mount an appropriate insulin response to a glucose challenge, islets were isolated from 19 week old mice and insulin secretion assayed. The observed insulin secretion differed slightly in the two mutant ENU alleles compared to the heterozygous global knockout. All 3 alleles secreted insulin in response to increasing glucose concentrations and to the tolbutamide treatment control (Figure 3E). Both Mll2M2628K/+ and Mll2F2648I/+ alleles secreted significantly more insulin at 2 mM glucose, resulting in a lower fold change difference in secretion at 10 and 20 mM, which would appear to mirror the lack of increased insulin secretion observed in the whole animal studies (Figure 3F). Islets from mice heterozygous for the global Mll2 knockout also secreted more insulin at 2 mM glucose although this did not reach statistical significance, however they secreted significantly less insulin at 10 mM glucose compared to wild-type littermate controls and had lower fold change differences at 10 and 20 mM glucose. Data from isolated islets is consistent with whole animal data; fasting hyperinsulinaemia and greatly reduced fold increase secretion of insulin in response to a glucose challenge.
Tamoxifen induced Knockdown of MII2 in adult mice does not result in a glucose phenotype

In order to test whether the observed adult glucose phenotype was the result of early developmental effects or changes in the adult animal we carried out a heterozygous adult-induced knockout. A floxed MII2 allele was crossed with a tamoxifen-inducible ubiquitin-Cre and mice of all genotype classes treated with tamoxifen or vehicle at 8 weeks of age, in order to generate a knockout allele. Mice were phenotyped at 12 weeks using an IPGTT test. No significant difference was seen in either glucose tolerance, weight or fasted insulin in heterozygous mice (Figure 4A, B and C and Figure S4). Levels of MII2 knockdown in tamoxifen treated mice was assayed by quantitative RTPCR (Figure 4D) and 41% reduction in MII2 levels was observed.

Biochemical and histological analysis of MII2 mutants; evidence of fatty liver disease

As these mice were insulin resistant we further investigated them for other metabolic disturbances. At 19 weeks of age mice were fasted for four hours then sacrificed and metabolic tissues were collected, additionally epididymal white fat pads and livers were weighed. The two mutant ENU alleles of MII2 exhibited dyslipidemia and epididymal fat pads were significantly lighter at 19 weeks of age in the mutants versus wild-type littermates (Figure 5A). They also showed significant hepatomegaly compared to wild-type littermates (Figure 5B). There was no significant increase in body mass observed in the 2 ENU mutants or MII22/2 knockdown compared to wild-type littermates. Body composition of the MII22/2;M2628K/+ mutant allele was additionally measured by DEXA analysis at 8, 12 and 18 weeks of age (Figure S3) with a brief increase in percentage fat mass observed at 12 weeks of age in the mutant (31.04±4.25% vs 26.85±4.87%). Histological analysis of liver sections demonstrated features consistent with NAFLD (Figure 5C–F). The severity was formally assessed using the semi-quantitative NIDDK histological score [31] and revealed significant increases in steatosis and ballooning hepatocyte degeneration compared to wild-type littermates. Biochemical analysis of plasma samples showed significantly increased cholesterol and triglyceride (Figure 5G and H). Biochemical analysis of liver tissue showed increased triglyceride and free fatty acid content in MII22/2;M2628K/+ compared to wild-type littermates (Figure 5I).

Histological analysis of Pancreatic Islets

Pancreatic sections from MII22/2;M2628K/+ animals and wild-type littermates were examined for differences in both islet mass and architecture, 3 sections for 8 mice of each genotype class were examined. There was small significant increase (p<0.01) in islet area in heterozygous MII22/2;M2628K/+ mice (1.237±0.077%) compared to wild-type litter mates (1.002±0.358%) in their percentage of islet areas (the percentage of a histological section identified as islet Table S2). Histological staining showed no qualitative

difference in islet architecture in terms of arrangement or relative numbers of α- or δ-cells (data not shown)

Altered gene expression in Mll2 mutants

The H3K4 methyltransferase Mll2 is thought to function briefly during development to alter cellular gene expression programmes that are then maintained by other redundant mechanisms [37]. This is consistent with our results as the adult knockout suggests that the glucose phenotype arises from changes in gene expression during development to alter cellular gene expression programmes (Figure S6). The expression profile of these downregulated genes was investigated in adult Mll2+/+/− heterozygous mutants in the metabolically important tissues liver, white adipose tissue, isolated islets and skeletal muscle (Figure 6A–D).

Neurod1 is an important transcriptional regulator both in the developing pancreas and the mature beta cell. Its expression was significantly downregulated in mutant islets, therefore the relative expression of a number of genes regulated by Neurod1 in the beta cell were examined. Ins1 but not Ins2 insulin gene expression was slightly upregulated, and both Glucagon and Nnat downregulated (Figure S6). Nnat expression was significantly reduced in liver and white adipose tissue (Figure 6A and B). Slc27a2 expression was significantly reduced in islets and adipose tissue. There were no significant difference in liver or muscle (although a trend to reduction in the latter) (Figure 6A–D). Eupp1 and Eupp3 showed a significant increase in skeletal muscle and Eupp3 showed no difference (Figure 6D).
Phosphatidylinositol-specific phospholipase C, X domain containing 1 (Plcxd1) expression was reduced in all tissues examined.

Discussion

We have identified two mutations in the histone methyltransferase Mll2, within the highly conserved carboxyl-terminal SET domain which is required for methyltransferase activity. Overlaying the two mutations on the recently determined crystal structure...
of its sister gene MLL1 places the MLL2 M2628K mutation within the active site and the MLL2 M2628I mutation within the α5 helix of the SET-C domain [34]. Both mutations are embryonic lethal when homozygous or when crossed to a global Mll2 knockout as expected, confirming both mutant alleles are nulls and abolish methyltransferase activity. This loss of activity has been further illustrated in vitro by the substitution of the mutant MLL2 M2628K amino acid into the highly conserved sister gene MLL1. When the mutation is introduced into the SET-domain of MLL1, there is impaired mono-methylation of H3K4 in vitro.

Haploinsufficiency of Mll2 results in hyperglycaemia and hyperinsulinemia at fasting and impaired glucose tolerance with blunted insulin secretion in response to a glucose load. Insulin tolerance tests further showed peripheral insulin resistance, with a reduced fold change in insulin secretion observed in isolated islets. Mice have no increase in body mass and mostly no difference in body composition. However, they exhibit abnormal plasma triglycerides, total cholesterol and reduced fat pad mass with concurrent hepatomegaly and increased hepatic fat accumulation when culled at 19 weeks of age.

NAFLD is a complex genetic trait strongly associated with type 2 diabetes and insulin resistance and is increasingly recognised as the leading cause for liver dysfunction and cirrhosis in the non-alcoholic, viral hepatitis negative population in Europe and North America [38–40]. The NAFLD phenotype spontaneously develops in Mll2 mutants and may be in response to insulin resistance or alternatively may cause a pre-disposition to NAFLD.

As methylated H3K4 is associated with active chromatin, reduced MLL2 protein levels or H3K4 methyltransferase function could lead to changes in transcription of genes. A published inducible knockout of Mll2 used expression profiling of ES cells to show that only a single developmental gene, Magel2, is entirely dependent upon Mll2 for its expression [37]. Knockout of Mll2 after E11.5 produced mice without noticeable pathologies suggesting Mll2 is not required for late development, stem cells or homeostasis in somatic cells, although male mice lacking Mll2

Figure 5. Biochemical and Histological analysis of Mll2 mutants; NAFLD and dyslipidaemia. Cohorts of mice were culled at 19 weeks of age. A: Epididymal fat pad weights normalized for body weight, Mll2 M2628K+/− (N = 10) and Mll2 F2628I+/− (N = 7) cohorts exhibited abnormal peripheral fat deposition with reduced fat pads compared to wild-type littermates (N = 23) or Mll2+/+ (N = 10) and Mll2 M2628K+/− (N = 7) cohorts show hepatomegaly. C–D: Histological analysis of H&E stained liver sections demonstrated features consistent with mild NAFLD in all Mll2 mutant and knockout lines (Figure 6C, D & E) with significant increases in macrovesicular steatosis (black arrow), microvesicular steatosis (red arrows) and ballooning hepatocyte degeneration (white arrow), compared to wild-type littermates. Biochemical analysis of plasma showed elevated Cholesterol (G) and Triglycerides (H). I: The steatosis was confirmed biochemically as liver triglycerides and liver free fatty acids were significantly increased in the M2628K mutation. The data represent the mean of 6 animals of each genotype class ±SEM * p<0.05, **p<0.01, ***p<0.001, student’s t-test.

doi:10.1371/journal.pone.0061870.g005
are infertile. We observed altered mRNA levels of a number of genes shown to be downregulated in these studies [37].

Neurod1, downregulated in mutant islets, is required for the regulation of β-cell genes including Insulin, Sulphonylurea Receptor (Sur1), Glucagon, Somatostatin and Neuronatin (Nnat). Ins1 was moderately upregulated in islets, probably as a result of the insulin resistance leading to hyperinsulinaemia. Sur1 a component of the KATP channel essential for glucose stimulated insulin secretion was unchanged. Somatostatin was upregulated and it has been proposed to exert an inhibitory effect on insulin and glucagon secretion, and may contribute to the insulin dysregulation, although its physiological significance in these roles is unclear (see for example [41,42]). Glucagon stimulates glucose mobilization and its downregulation may reflect the hyperglycaemia.

The greatest difference observed was reduced Nnat gene expression. Nnat is an imprinted gene expressed from the paternal allele and CHIP assays suggest that Nnat is a direct target of Neurod1 [43]. Increased expression of Nnat results in increased insulin secretion upon acute glucose stimulation and knockdown of Nnat in insulin secreting cell lines resulted in a loss of glucose stimulated insulin secretion [43,44]. The decrease in Nnat expression may explain the reduction in glucose stimulated insulin secretion that we observed. Nnat is also abundantly expressed in adipose tissue and has a role in the potentiation of adipocyte differentiation [43]. Nnat potentiates adipogenesis through enhanced phosphorylation of cAMP-response element-binding protein in 3T3-L1 cells [46], and is upregulated in Zucker diabetic rats compared to control lean Zucker rats [47]. It has also been associated with severe childhood and adult obesity in humans [48]. Nnat expression was significantly downregulated in epididymal fat from Mll2 mutant animals and may lead to reduced adipogenesis and a reduction in mature adipocytes reflected in the reduced fat pad mass observed.

Slc27a2 (FATP2) is one of the 2 main fatty acid transporters in the liver, with knockdown of expression shown to reduce long chain fatty acid (LCFA) uptake by 40% [49]. This gene was strikingly reduced in expression in islets and adipose tissue. Interestingly, as reduction of FATP2 has been shown to protect against hepatosteatosis on a high fat diet, there was no difference in liver expression between mutant and wild-type and this may predispose to the steatohepatitis that we observed [49]. Why loss of Mll2 function does not lead to a reduction of Slc27a2 expression in liver but does reduce expression in islets and fat and indeed in ES cells [37] is unclear.

Both Enpp3 and Enpp1 have both been associated with diabetes. ENPP3 protein was detected in rat pancreas and liver and downregulated in islets by high compared to low glucose in diabetic GK rats, consistent with our observations [50]. Variants of ENPP1 in human GWAS studies have been associated with obesity, type 2 diabetes and a primary role in insulin resistance [51]. Increased expression of Enpp1 or its overactivity is correlated with insulin resistance, through direct effects in the insulin signaling pathway. This may explain, at least in the case of increase Enpp1 expression in skeletal muscle, some of the insulin resistance in our mutant mice (reviewed [52]).

Phospholipases are responsible for the hydrolysis of phosphatidylinositol 4,5-biphosphate (PIP2) to inositol 1,4,5-triphosphate (IP3) and 1,2-diacylglycerol (DAG), both of which have important second messenger functions. Phosphatidylinositol-specific phospholipase C, X domain containing 1 (Pldx1) was shown to be significantly downregulated in all tissues examined. There is limited information about the function of this gene but reduced

Figure 6. Relative expression of Mll2 regulated genes. A: Liver, B: Epididymal White adipose, C: Isolated islets, D: Skeletal Muscle. Data represents 8 biological replicates, Mll2M2628K/+ (open bars) vs wt littermates, (black bars) data normalized to GAPDH. Relative expression ±SEM * p<0.05, **p<0.01, ***p<0.001, student’s t-test. nd = not detectable. doi:10.1371/journal.pone.0061870.g006
expression may reflect dysregulation of insulin signalling pathways either through effects on IP3 or DAG.

Type 2 Diabetes is a complex disease involving many different tissue types, euglycemic hyperinsulinemic CLAMP studies may further dissect the tissues important for the insulin resistance identified in this model. CHIP studies in relevant tissues may identify other yet unidentified genes whose regulation by MLL2 at the chromatin level may contribute to disease. It would be informative to carry out these studies before and after onset of overt disease to differentiate between causal and effect differences in gene expression. Whilst the mutation identified is in a single gene MLL2 the phenotype observed is likely to be the result of multiple small changes in the expression of a number of genes in many diverse tissues. Tissue specific KO of MLL2 followed by CHIP analysis and comprehensive metabolic phenotyping should yield insight into the relative contribution of each tissue and gene set to onset of disease.

Conclusions

In summary, we have identified two ENU induced point mutations M2628K and F2628I in MLL2 that give rise to a novel murine model of insulin resistance, impaired glucose tolerance and primary stages of NAFLD. We have provided evidence that these are functional mutations that affect the H3K4 methyltransferase activity of MLL2 that then leads to changes during embryonic development, likely in chromatin and DNA methylation (see [37]), that determine the expression of genes linked to diabetes phenotypes in the adult. These data reveal that gene expression controlled through histone methylation is a significant mechanism involved in glucose homeostasis.

Supporting Information

Figure S1 Sequence alignment of the highly conserved SET domain of MLL1 and MLL2.

Figure S2 In vitro methyltransferase assays indicate a reduced activity of the MLL1 (M3884K) mutant in comparison to wild-type MLL1. The methylation of histone H3 substrates comprising the first 21 N-terminal amino acids was quantified enzyme linked immunoabsorbent assays (ELISAs) with antibodies against H3K4me1, me2 and me3. A: Unmodified H3 peptide (H3K4me0) was incubated with wild-type and mutant recombinant expressed SET-domain of MLL1 respectively and product detected (see Figure S3 for time courses of the subsequent products H3K4me2 and H3K4me3). B: Monomethylated H3 peptide (H3K4me1) was incubated with MLL and samples were analyzed for dimethylation (forming H3K4me2 - Figure S3 for time courses of the subsequent product H3K4me3). C: Dimethylated H3 peptide (H3K4me2) was incubated with MLL and H3K4me3 product detected. The activity of the M3884K was reduced compared to wild-type in all cases. The M3884K position of MLL1 is equivalent to the M2628K position of MLL2 based on sequence alignment. Error bars show the SD from the mean value of three experiments.

Figure S3 In vitro methyltransferase assays indicate a reduced activity of the MLL1 (M3884K) mutant in comparison to wild-type MLL1. The methylation of histone H3 substrates comprising the first 21 N-terminal amino acids was quantified enzyme linked immunoabsorbent assays with antibodies against H3K4me1, me2 and me3. A–C: Unmodified H3 peptide was incubated with wildtype and mutant recombinant expressed SET-domain of MLL1 respectively. Samples were analyzed for (A) monomethylation, (B) dimethylation and (C) trimethylation at lysine 4 after 2, 8, 20 and 48 hours. D, E: H3 peptide with a monomethyl modified lysine 4 was incubated with the enzyme and the mutant. The samples were analyzed for (D) dimethylation and (E) trimethylation. F: Lysine 4 dimethyl H3 peptide was incubated with the wild-type enzyme and mutant and samples analyzed for a trimethyl mark at lysine 4. Error bars show the SD from the mean value.

Figure S4 Adult Knockout of Mll2. All genotype classes and treatment groups. N = 7–11 for each group. A: Plasma glucose measured in an intraperitoneal glucose tolerance test in male mice at 12 weeks of age, B: Weight at 12 weeks of age, C: Fasted plasma insulin at 12 weeks of age. Data represented as Mean ± SEM.

Figure S5 Dexta analysis of Mll2M2628K/+ compared to wildtype litter mates. Dexta analysis at 8, 12 and 18weeks Mll2M2628K/+ (open bars N = 12) compared to wildtype littersmates (Black bars N = 17). No significant difference was observed in total body weight or lean mass at any of the 3 time points. A transient significant increase in body fat in Mll2M2628K/+ was observed at 12 weeks of age (p = 0.03). Data represented as Mean ± SEM.

Figure S6 Relative expression of Neurod1 regulated genes in isolated Islets. Data represents 8 biological replicates, Mll2M2628K/+ (open bars) vs wt littermates (black bars), data normalized to GAPDH. Relative expression ± SEM * p<0.05, **p<0.01, ***p<0.001, student’s t-test
