ABSTRACT

Ectopic Cushing’s syndrome (CS) is rare and difficult to cure when the source is elusive. Medical management is complex and often times contraindicated in the medically complex patient. We present a complicated case of ectopic CS where bilateral percutaneous microwave ablation (MWA) of the adrenal glands successfully cured hypercortisolism when surgery and medical therapies were contraindicated. A 71-year-old male was diagnosed with ectopic CS after adrenocorticotrophic hormone-dependent hypercortisolism persisted after hypophysectomy despite a positive gradient of >3 on inferior petrosal sinus sampling. An ectopic source was not identified. Surgery and medical therapies were contraindicated due to comorbidities and drug interactions. Bilateral MWA of the adrenal glands was performed. Postprocedurally cortisol levels declined and the patient was clinically adrenally insufficient at 6 months. Bilateral MWA of the adrenal glands can prove to be an effective treatment option for ectopic CS when surgical resection and medical therapies are ineffective or contraindicated.

Introduction

Cushing’s syndrome (CS) is associated with significant morbidity and mortality [1]. The ultimate goal is cure by surgical resection of the primary source [2]. In ectopic CS, however, identification of the primary source can be difficult, with a 1–20-year delay in finding the tumor and up to 16% of cases the tumor is not found [3]. Medical therapy is recommended to treat hypercortisolism if surgery is delayed or contraindicated.
Medical management, however, is complex, as all available treatment modalities have numerous side effects, require intense follow-up for medication titration, are either expensive or difficult to source, and have lower efficacy rates compared to surgery [2,4]. Here, we present a complicated case of ectopic adrenocorticotrophic hormone (ACTH)-dependent CS successfully treated with bilateral percutaneous microwave ablation (MWA) of the adrenal glands.

Three months after initial presentation, he developed abdominal wall cellulitis, sepsis, and a DVT for which he was started on apixaban 5 mg twice a day. He underwent inferior petrosal sinus sampling 6 months after initial presentation, which was significant for a central-to-peripheral plasma ACTH gradient of 3.7 after corticotropin-releasing hormone administration (Table 2). He was started on ketoconazole 200 mg every 8 hours while awaiting surgery. Trans-sphenoidal surgery was performed 11 months after initial presentation. Pathology revealed pituitary hyperplasia with positive staining for ACTH. However, he had persistent hypercortisolism after initial surgery (Table 1) and was restarted on ketoconazole 200 mg every 8 hours.

He underwent repeat trans-sphenoidal surgery with hypophysectomy and distal stalk resection 15 months after initial presentation, for which the pathology showed pituitary gland composed of small cells with minimal pleomorphism. ACTH staining was positive in many of the pituitary cells. A reticulin stain demonstrated expanded acini focally. Unfortunately, elevated ACTH and cortisol levels persisted despite the development of central hypothyroidism and a decrease in pro lactin post operatively (Table 1). These findings confirmed ectopic Cushing’s syndrome. Possible ectopic sources were an incidental 10 mm lung nodule and a 3 cm thyroid nodule.

Table 1 – Laboratory results before and after trans-sphenoidal pituitary surgery and bilateral adrenal gland percutaneous microwave ablation.

Case presentation

A 71-year-old male with a past medical history of hypogonadotropic hypogonadism, obesity (BMI 39.5 kg/m²), type 2 diabetes mellitus (T2DM) diagnosed 4 years prior, and obstructive sleep apnea diagnosed 1 year prior, initially presented for management of T2DM. The patient reported significant weight gain, thinning of the skin, and easy bruising which prompted evaluation and confirmation of ACTH-dependent CS (Table 1). A pituitary protocol brain MRI was unable to identify a discrete pituitary lesion.
that were both noted on prior scans. Unfortunately, due to his multiple comorbidities, surgical resection of the lung nodule, thyroid nodule or both adrenal glands were too risky. After a multidisciplinary team meeting which included endocrinology, neurosurgery, interventional radiology, family members and the patient, bilateral MWA of the adrenal glands was performed (Fig. 1) after pre-procedure alpha blockade with doxazosin. The procedure was uncomplicated except for a brief (45 seconds) period of hypertension with systolic blood pressure reaching 200 mmHg.

After bilateral adrenal gland MWA, the patient had an immediate decrease in serum cortisol levels (Fig. 2). On MWA post-op day 5, the patient was started empirically on hydrocortisone and fludrocortisone due to symptoms of adrenal insufficiency with nausea and hypotension. These were tapered off as an outpatient over the course of 4 months given an 0800 AM serum cortisol of 16.4 ug/dl, which was measured off hydrocortisone for 24 hours. Six months after his MWA, he was hospitalized for septic shock due to pneumonia, and was found to have a low 0800 AM serum cortisol of 4.6 ug/dl (Table 1), with a low sodium of 131 mmol/L (136-144 mmol/L) and a high potassium of 5.1 mmol/L (3.3-5.0 mmol/L). He was treated with stress dose steroids, and then restarted on hydrocortisone and fludrocortisone for primary adrenal insufficiency. He had 2 repeat 8 AM cortisol concentrations off hydrocortisone which were both consistent with adrenal insufficiency (Table 1).

At his 1- and 2-year follow-up post-MWA of his adrenal glands, he was improving clinically. He had 13 kg weight loss with improvements in both his blood pressure and glycemic control. He continues on hydrocortisone and fludrocortisone replacement.

**Discussion**

Here, we present a complicated case of ectopic CS whose hypercortisolism was successfully cured with bilateral adrenal MWA. Surgery is the primary treatment modality for CS. In ectopic CS, however, the source can be elusive [3]. In our case, inferior petrosal sinus sampling suggested a pituitary source. Despite anterior hypophysectomy, our patient’s hypercortisolism persisted. Given his overall comorbidities, prompt treatment of his hypercortisolism was of utmost importance. Unfortunately, the risks associated with both medical therapy and open bilateral adrenalectomy were too risky. Bilateral adrenal gland MWA was therefore the best and least invasive option to effectively treat his hypercortisolism.

Medical treatment of CS consists of osilodrostat, mitotane, mifepristone, ketoconazole, and/or metyrapone. All options are associated with significant side effects and have many drug interactions [5]. In our case, concomitant use of ketoconazole and apixaban can result in elevated levels of apixaban predisposing to bleeding. Our patient’s cardiac and thrombosis comorbidities made the use of other medical options too risky. In addition, metyrapone was not easily accessible and

* Year article was published and country of authors.

Rapidity to improve hypercortisolism was critical. Ventilation was to be avoided, thus etomidate was not chosen. Etomidate is also a bridge therapy and unable to be used long term. In one cohort with 76 patients with ectopic CS, only 13% (n = 7) treated with medical therapy had normalization of cortisol [6]. On the other hand, all who underwent surgical bilateral adrenalectomy had biochemical cure [6].

Bilateral adrenalectomy is recommended when medical therapy is contraindicated or if hypercortisolism is severe and surgical resection of the source is unattainable [4,5]. Adrenal gland ablation is a less invasive approach for patients who may not be good candidates for surgery or medical therapy, or have failed conventional therapy or other treatment modalities. Thermal ablation, including cryoablation, radiofrequency ablation (RFA) and MWA, is primarily utilized to treat focal oncologic lesions. MWA uses electromagnetic energy in the microwave range to agitate water molecules resulting in frictional heat and cellular death via necrosis, whereas RFA uses electrical current produced by a radiowaves [7,8]. The primary use of thermal ablation of the adrenal glands is in the treatment of primary or metastatic adrenal neoplasms. There are several successful case studies treating functional unilateral
adrenal neoplasms with thermal ablation [9]. In one report, there was a 100% response rate with unilateral RFA to treat 13 functional adrenal tumors (primary hyperaldosteronism, n = 10; pheochromocytoma, n = 1; cortisol-secreting tumors, n = 1; testosterone-secreting tumor, n = 1) [9]. In a slightly smaller case series (n = 11), there was a 91% resolution when unilateral RFA was used to treat functional adrenal tumors (primary hyperaldosteronism, n = 9 and cortisol-secreting tumor, n = 2) [10].

While there are several studies reporting unilateral adrenal gland ablation, there are scattered case reports of bilateral adrenal gland ablation. A review of the literature was only able to identify 4 cases reported in the literature of patients who have undergone a bilateral adrenal MWA for ACTH dependent hypercortisolism, 5 cases utilizing RFA, and 2 cases treated with alcohol ablation (Table 3). As in our case, nearly all patients had already failed conventional therapy prior to undergoing bilateral adrenal ablation. Most patients had a good response after the procedure with only 1 patient out of 11 who had undergone bilateral alcohol ablation failing to show significant decrease in cortisol levels and required medical treatment afterward [11]. One patient who underwent MWA responded to therapy, but then underwent surgical bilateral adrenalectomy after improving clinically [4]. All the patients who underwent either bilateral MWA or RFA had a decrease in cortisol levels. Of those undergoing MWA/RFA, all patients had good clinical outcomes with weight loss, improved blood pressure and glycemric control, resolution of electrolyte abnormalities and increased bone mineral density. Half of the patients who underwent bilateral adrenal gland ablation developed adrenal insufficiency requiring steroid replacement, suggesting significant destruction of the adrenal gland tissue. The time to adrenal insufficiency, however, was variable. Either adrenal insufficiency occurred immediately after surgery or the timing was difficult to deduce because patients were started on hydrocortisone preemptively. In our case, the time to develop adrenal insufficiency took several months after bilateral adrenal gland MWA. Larger studies are needed to determine the range of time for patients to developed adrenal insufficiency after bilateral adrenal ablation.

**Conclusion**

Bilateral adrenal gland MWA effectively cured hypercortisolism in our patient with ectopic CS. Despite our patient’s medical complexities, bilateral adrenal gland MWA induced a clinical cure without the increased risks associated with bilateral adrenalectomy and complexities of medical management in high-risk patients. Bilateral adrenal MWA should be considered as an effective treatment modalities for CS.

**Patient consent**

A written, informed consent from the patient was obtained to publish the patient’s case in this journal.
