Abstract

We systematically investigate the links between price returns and ESG features. We propose a cross-validation scheme with random company-wise validation to mitigate the relative initial lack of quantity and quality of ESG data, which allows us to use most of the latest and best data to both train and validate our models. Boosted trees successfully explain a single bit of annual price returns not accounted for in the traditional market factor. We check with benchmark features that ESG features do contain significantly more information than basic fundamental features alone. The most relevant sub-ESG feature encodes controversies. Finally, we find opposite effects of better ESG scores on the price returns of small and large capitalization companies: better ESG scores are generally associated with larger price returns for the latter, and reversely for the former.

1 Introduction

Investing according to how well companies do with respect to their environmental, social and governance scores is very appealing for a growing number of investors. Beyond moral criteria, such kind of investments may increase the value of high-ESG scoring companies, which will attract even the non-ESG minded investor, thereby starting a virtuous circle both for the investors and for the beneficiaries of high ESG scores, leading to successful impact investing whereby an investor generates positive environmental or societal impact while targeting a specific level of return (Townsend, 2020; Grim and Berkowitz, 2020).

From a quantitative point of view, ESG features raise the question of their information content. Friede et al. (2015) aggregated the results of more than 2200 studies: 90% of them showed a non-negative relation between ESG and corporate financial performance measures, a majority displaying a positive performance. However, more recently, Cornell and Damodaran (2020); Breedt et al. (2019); De Franco et al. (2020) reach less clear-cut conclusions. Our aim is to clarify this issue. The real question in our view is whether ESG features contain additional information with respect to well-known factors.

The current situation is mostly caused by the specific challenges that ESG data provide: i) they are quite sparse before 2015, as the interest of even computing such scores is quite recent; ii) they are usually updated yearly iii) the way they are computed often changes as a function of time and may
depend on the way companies disclose data; iv) human subjectivity may be involved to a large extent
in the computation of the scores.

This work is devoted to overcome these challenges first by using high-quality data, and by testing
several model validation schemes, including random company-wise cross-validation that makes it pos-
sible to use most of the latest data to train models. The resulting methodology is robust enough to
yield clear answers.

2 Datasets

2.1 Financial data

We use the following data sets:

- Stock prices. We use daily close prices, adjusted for dividends and foreign exchange rates. BNP
  Paribas internal data sources.

- Market capitalization. BNP Paribas internal data sources.

- Fama-French market, size and value factors: these factors are taken from the online French data
  library Fama and French [2021]. They are all computed according to the Fama and French
  methodology exposed in Fama and French [1993].

- Risk-free rate: this data is also taken from Fama and French [2021] and computed according to
  the Fama and French method.

In addition, metadata like the TRBC Sector at levels 1, 2 and 3 and the country of incorporation
are used and come from Refinitiv data sources.

2.2 ESG Data

ESG data are provided by Refinitiv. Their database alleviates some of the challenges listed above:

1. the coverage of the dataset is sufficient to extract meaningful results. Figure 1 shows the number
   of samples in the geographical regions as defined by Fama and French [Fama and French, 2021]:
   Europe, North America, Japan, Asia-Pacific excluding Japan and Emerging Countries. Refinitiv
   ESG data start in 2002 and the number of samples per year increased by several folds until 2019,
   as shown in Fig. 2. The drop in 2020 is due to the fact that not all the ESG scores had been
   computed by Refinitiv when we had access to the dataset (many companies had not yet published
   enough data). It will not be an important issue as training does not take place in 2020 but it
   may have an impact on the test results of this particular year.

2. Scores are built with a well documented methodology explained in Refinitiv [2021]. Every ESG
   score ranges between 0 and 1, 1 being the best score. In addition, the same methodology is used
   throughout the years, yielding consistent data.

3. Human intervention is limited in the building of this ESG dataset, which eliminates as most as
   possible human subjectivity: the methodology is quantitative, limiting human intervention to
   some quality checks.
Figure 1: Number of samples in each Fama-French region in the Refinitiv ESG dataset.

4. Scores can be updated up to 5 years after first publication, which is beneficial in an explanatory setting, as the data become more accurate. In a purely predictive setting however, this adds noise and look-ahead bias as we do not have point-in-time data, i.e., we do not know the initial and intermediate ESG estimates.

Refinitiv ESG data includes samples from different regions of the world. Each region has specific regulatory frameworks and ESG transparency rules. This is why this paper focuses on the European region and includes all the companies in the Refinitiv ESG dataset whose country of incorporation is in Europe or in a European-dependent territory.

The European ESG dataset contains 20509 samples for 2429 companies uniquely identified by their ISIN. The time evolution of the number of samples per year is reported in Fig. 3. All the sectors have enough data, with the notable exception of the Academic and Educational Services sector (see Fig. 4).

3 Methods

3.1 Problem settings

Our goal is to understand how and what ESG features participate in the formation of price returns. More precisely, we examine whether ESG features bring additional information with respect to well-known factors. In a multi-factor model, one writes at time $t$

$$r_{i,t} = r_{f,t} + \sum_k w_{i,k} F_{k,t} + \alpha_i + \epsilon_{i,t}$$  \hspace{1cm} (1)

where $r_{i,t}$ is return of asset $i$, $r_{f,t}$ the risk-free rate, $F_{k,t}$ the value of factor $k$ at time $t$ and $w_{i,k}$ is the factor loading; the idiosyncratic parts are $\alpha_i$, the unexplained average return, and the zero-average residuals $\epsilon_{i,t}$. In this work, we use the CAPM model and its extension, the Fama-French 3-factor model that includes market ($r_m$), size (SMB), and value (HML) factors [Fama and French, 1993].
Figure 2: Time evolution of the number of samples in the Refinitiv ESG dataset.

Figure 3: Time evolution of the number of samples per year in the Refinitiv ESG dataset - Europe.
Figure 4: Number of samples for TRBC L1 Sector in the Refinitiv ESG dataset - Europe.
When data is abundant and of constantly high quality, the determinants of the idiosyncratic part can be found with standard tools. However, in our case, we must settle for a less ambitious goal. We investigate indeed here the most basic question: can ESG features help explain the sign (i.e., a single bit) of the idiosyncratic part of price returns? Mathematically, one needs to explain

$$Y_{i,t} = \frac{1 + \text{sign}(\alpha_i + \epsilon_{i,t})}{2}$$

with the candidate features.

This work takes a machine learning approach to this problem and treats it as a classification problem: $Y_{i,t}$ defines two classes as it can take two values. Thus, for each possible couple $(i, t)$, one has a vector of $D$ potentially explanatory factors, called features in the following. Let us relabel all the couples $(i, t)$ by the index $m \in \{1, \cdots, n\}$. The classification problem consists in explaining $Y_m$ by a vector $X_m$ with $D$ components, or equivalently, to explain the vector $Y \in \{0, 1\}^n$ from the lines of matrix $X \in \mathbb{R}^{n \times D}$. $Y$ is called the target and $X$ the feature matrix. The problem is then to train a machine learning method to learn the mapping between the lines of $X$ and the components of vector $Y$. Once the training is complete, such a model takes as input a vector of features and outputs the probability that these features correspond to one class (in a two-class problem).

The state of the art in that area is provided by Gradient Boosting models (Friedman, 2001), as shown for instance in Shwartz-Ziv and Armon (2021). The spirit of gradient boosting consists in using a sequence of weak learners (wrong models) that iteratively correct the mistakes of the previous ones, which eventually yields a strong learner (good model). We use here decision trees as weak learners. Different implementations of the Gradient Boosted Decision Trees method exist, e.g. XGBoost (Chen and Guestrin, 2016), LightGBM (Ke et al., 2017), CatBoost (Prokhorenkova et al., 2017). We use here LightGBM. The advantage of such methods with respect to logistic regression is that they are able to learn more generic functional forms.

The models are trained to minimize the cross-entropy (cost function), also known as LogLoss, defined as

$$L = -\frac{1}{N} \sum_{i=1}^{N} y_i \log(p_i) + (1 - y_i) \log(1 - p_i),$$

where $p_i$ is the model probability that sample $i$ belongs in category 1 and $y_i$ is the true class (which selects for each $i$ the suitable term of the sum). This type of loss implicitly assumes that both true classes appear with roughly the same frequency in the training set, which is the case with 51.7% of samples belonging to class 1 and 48.3% to class 0.

### 3.2 Training features

Refinitiv ESG dataset contains several levels of granularity. We choose to train our models with the 10 pillar scores described in Appendix A (Resource Use, Emissions, Innovation, Workforce, Human Rights, Community, Product Responsibility, Management, Shareholders, CSR Strategy) and the aggregated Controversy score. This level of granularity is a good compromise.

We add five non-ESG features (market capitalization, country of incorporation and TRBC Sector at levels 1, 2 and 3). These features provide the benchmark features needed to settle the question of the additional information provided by ESG features.
3.3 Target computation

We compute the coefficients of the regression defined in Eq. 2 with monthly factors available on-line at [Fama and French (2021)] and monthly price returns over periods of 5 civil years. For instance, the regression coefficients used to compute the 2017 target possibly explained by 2017 ESG features are computed with historical data ranging from 2013 to 2017. We then compute targets over the year corresponding to the year of the ESG features.

3.4 Cross-validation and hyperparameter tuning in an increasingly good data universe

The usual strategy of a single data split into causal consecutive train, validation and test data sets may not be fully appropriate for the currently available ESG features. This is because the amount of data grows from a very low baseline both quantity– and quality–wise that was not exploitable to an amount that more likely is. Thus, not only the data is non-stationary, but its reliability and quality keeps increasing. As a consequence, the cross-validation time splitting schemes known to work well in the context of non-stationary time series ([Bergmeir and Benitez 2012]) may be improved on.

For this reason, we experiment with $K$-fold company-wise cross-validation where 75% of companies are randomly assigned to the train and the remaining 25% ones to the validation set (see Fig. 5). In this way, models are trained with most of the most recent (hence, more relevant) data, while validating the model also with the most recent and best data. If the dependencies completely change every year, this validation scheme is bound to fail. As we shall see, this is not the case. We take $K = 5$. 

Figure 5: Company-wise cross-validation: the validation sets consists on randomly selected companies, which allows training to account for most of the most recent data.
Figure 6: Company-wise cross-validation: test set cross-entropy versus validation cross-entropy of the 100 best models of the random hyperparameters search.

In addition, we use expanding (train+validation)-test windows, using the last year as the test window, which allows us to perform a time-wise analysis of the performance of the models. Because data is insufficient before 2015, the first test year is 2016 and the last one is 2020. We thus train and validate 25 models.

For each testing period, we will compare the performance of the company-wise 5-fold random splits with that of the standard temporal split (75% train / 25% validation).

4 Results

We investigate here the results of the standard temporal split and the 5-fold company-wise split for a target computed using the CAPM model, as described in 3.1. Models trained using the Fama-French 3-factor model lead to less clear-cut performance; their results are relegated to Appendix B.

We first assess the quality of the models according to the cross-entropy loss, using their direct probability outputs. We also assess the end result, i.e., the predicted class. As it is usual, we map the output, a probability $p_i$, to classes 0 and 1 with respect to a 0.5 threshold. This allows us to compute the balanced accuracy, defined as the average of the sensitivity and the specificity. Sensitivity equals the ratio of true positives to the number of positive samples. Specificity is the ratio of the true negatives to the number of negative samples. An advantage of the balanced accuracy over classical accuracy is that balanced accuracy accounts for class unbalance in the test set. By definition, it assigns a score of 0.5 if the model did not learn anything significant.

We check that the performance of the models in the test sets bear some relationships with their
Company-wise 5-fold cross-validation

| Year | Pearson correlation | $R^2$ | Kendall tau | p-value of Kendall tau |
|------|---------------------|-------|-------------|------------------------|
| 2016 | -0.54               | 0.29  | -0.36       | 8.0e$^-8$              |
| 2017 | 0.14                | 0.021 | 0.12        | 6.7e$^-2$              |
| 2018 | 0.47                | 0.22  | 0.30        | 1.1e$^-5$              |
| 2019 | 0.73                | 0.54  | 0.58        | 1.5e$^-17$             |
| 2020 | 0.27                | 0.071 | 0.19        | 5.4e$^-3$              |

Standard temporal split

| Year | Pearson correlation | $R^2$ | Kendall tau | p-value of Kendall tau |
|------|---------------------|-------|-------------|------------------------|
| 2016 | -0.43               | 0.18  | -0.29       | 1.6e$^-3$              |
| 2017 | 0.46                | 0.21  | 0.33        | 9.2e$^-7$              |
| 2018 | 0.46                | 0.21  | 0.34        | 7.7e$^-7$              |
| 2019 | 0.47                | 0.22  | 0.33        | 1.3e$^-6$              |
| 2020 | 0.47                | 0.22  | 0.39        | 7.6e$^-9$              |

Table 1: Dependence measures between the cross-entropies in the validation and test sets, for the 100 best models of the random hyperparameters search.

performance in the validation sets. More precisely, for each (train/validation)+test period, we investigate the dependence between the cross-entropy losses in the validation and test sets for the best models trained during the hyperparameters random search, which makes it possible to characterize the training quality year by year. A significantly positive relationship shows that these models did learn persistent relationships, i.e., something useful and by extension that it makes sense to pool the best 5 of them. Mathematically, we assess the relationship $L_{\text{test}}^m$ versus $L_{\text{validation}}^m$ for each model $m$ ranking in the top 100 validation cross-entropy losses, for each of the five sets of (train+validation)/test sets. Figures 6a to 6e display these relationships for the company-wise cross-validation scheme and adds a linear fit (figures of the same type for the standard time splitting scheme can be found in Appendix C). Generally, both test and validation cross-entropy losses are positively correlated, except for 2016. We believe that this comes from the fact that ESG data were of insufficient quality before that date. Year 2020 is also special: in addition to the coronavirus crisis, the data for 2020 was obtained at the beginning of 2021 when not all companies had ESG ratings, leading to a smaller dataset and a (mostly likely) biased test set.

We compute the Pearson correlation, the $R^2$ of the linear fit, Kendall tau and its p-value for the standard temporal split and the 5-fold company-wise split, which are reported in Tab. 1. This latter allows us to compare the respective advantages and disadvantages of each validation strategy. All the dependence measures increase much from 2017 to 2019 for company-wise splits. The case of temporal split shows the limitations of this approach: the performance measures are roughly constant, which is consistent with the fact that adding one year of data to the train+validation dataset does not lead to much change. Display of the relationship $L_{\text{test}}^m$ versus $L_{\text{validation}}^m$ for the standard temporal model can be found in Appendix C in Fig. 16.

Our second and most important aim is to establish that ESG data contains additional useful and exploitable information. To this end, for each train period defined above, we train a model with both ESG and benchmark features and another one with the benchmark features only. We assess both the absolute performance measures of the models and the amount of additional information brought by ESG features by computing the difference of performance measures in the test sets.
Table 2: Performance measures on the test set for both types of validation splits. The numbers for the company-wise splits are the median values of the performance of 100 random samplings of 5 models among 100 random company-wise validation splits.

The company-wise splits make it easy to compute error bars on various measures: instead of training $K = 5$ models, we train 100 of them and then compute the median performance on 100 random subsets of size $K = 5$ among these 100 models. Table 2 provides results on absolute performance of the models for each test period, for both the company-wise and the standard temporal splits. Both splitting methods have a clearly decreasing cross-entropy as a function of time, except for 2020, which shows once again the special nature of this year in our dataset. This shows that the relevance of ESG features in price return formation increases as a function of time. Balanced accuracy displays a similar improvement before 2020. However, this time, company-wise splits yields increasingly better than temporal splits, which we believe is an encouraging sign of its ability to better leverage the latest and best data.

Figure 7 displays the time evolution of the cross-entropy and the balanced accuracy in the test sets. The boxplots are computed for the company-wise splits from the 100 associated predictions; the orange lines are the median of these performance measures, the rectangle delimits the first and third quartiles and extreme limits are situated before the first quartile minus 1.5 time the interquartile range and after the third quartile plus 1.5 time the interquartile range. Any point outside of this range is considered an outlier.

Company-wise 5-fold cross-validation outperforms the standard time splitting scheme, which supports our claim that the not fully mature nature of ESG data can be partly alleviated by a suitable validation scheme.

Figure 8 shows the difference of performance between the models trained on ESG and benchmark features and the models trained only on benchmark features, for the company-wise 5-fold cross-validation. ESG features contain more relevant information as time goes on. Two explanations spring to mind: long positions are more and more driven by ESG-conscious investors, or the quality of data increases as a function of time, which makes the relevance of ESG scores more apparent.
Figure 7: Performance measures on the test sets of the two train and validation schemes. The boxplots show the performance of 100 random samplings of 5 models among 100 random company-wise validation splits.

Figure 8: Performance measures in comparison to benchmark, for the company-wise 5-fold cross-validation.
5 Interpretability

In the remaining of this work, we provide a breakdown of the impact of the different ESG features on the predicted probability of having positive idiosyncratic returns. Because of the superior performance of the company-wise $K$-fold cross-validation, we use this method in the following.

5.1 Shapley values

Shapley values, first introduced in the context of game theory [Shapley, 1953], provide a way in machine learning to characterize how each feature contributes to the formation of the final predictions. Shapley values and their uses in the context of machine learning are well described in [Molnar, 2020].

The Shapley value of a feature can be obtained by averaging the difference of prediction between each combinations of features containing and not containing the said feature. For each sample in our dataset, each feature possesses its own Shapley value representing the contribution of this feature to the prediction for this particular sample. Shapley values have very interesting properties, one of them being the efficiency property. If we note $\phi_{j,i}$ the Shapley value of feature $j$ for a sample $x_i$ and $\hat{f}(x_i)$ the prediction for the sample $x_i$, Shapley values must add up to the difference between the prediction for the sample $x_i$ and the average of all predictions $E_X(\hat{f}(X))$ and then follow the following formula:

$$\sum_{j=1}^{p} \phi_{j} = \hat{f}(x) - E_X(\hat{f}(X)) \quad (3)$$

The dummy property also states that the Shapley value of a feature which does not change the prediction, whatever combinations of features it is added to, should have a Shapley value of 0.

Shapley values calculation is quite time and memory intensive. Lundberg and Lee (2017) and later Lundberg et al. (2018) proposed a fast implementation of an algorithm called TreeSHAP, which allows to approximate Shapley values for trees models like the LightGBM, which we use in the following and refer to as SHAP values.

Let us just note that, as we are using a LightGBM model in classification, the prediction is not directly the probability of belonging to the class 1, but rather the logit associated with this probability. Probability is an increasing function of the logit and thus SHAP values obtained for the logit can easily be transformed for the probability. Indeed, for a sample $x_i$, the predicted probability of belonging to class 1 $p_i$ is linked to the logit $\logit_i$ according to :

$$p_i = \frac{1}{1 + e^{-\logit_i}} \quad (4)$$

5.1.1 Evolution of ESG features contribution from 2017 to 2020

In Fig. 9, we plot for each feature its distribution of SHAP values for all test samples using box plots, for models trained from 2002 to 2016 (9a) and trained from 2002 to 2019 (9b). The first teaching of this plot is that the contribution of ESG features to the predicted probability of having a positive return has not dramatically increased with the additional, more recent and more complete data. Benchmark features are the ones which have the biggest impact on the prediction. However, we observe an important number of outliers for some SHAP values associated with some features, demonstrating that these ESG features have more impact on the prediction for these particular samples. It would
be interesting to study these outliers to understand more why ESG features are more important in explaining past returns for some samples than others.

For instance, we observe in Fig. 10 the scores distributions for the outliers of the Controversy SHAP values. All of these scores are below 0.9, suggesting that the Controversy score is more informative when a company has indeed suffered controversies during the year and was then not able to reach a score of 1. Observing outliers of SHAP values and their associated scores, we can make the hypothesis that ESG features are important and have a strong impact in the explanations of past returns if their score is extreme. This would mean that ESG information would lie in extreme scores, more standard scores bringing much less information. Checking this hypothesis is beyond the scope of this work and is left for future investigations.
5.2 Partial dependence plots

5.2.1 Definition

A partial dependence plot shows the marginal effect features on the prediction made by the model. It is a way of understanding the links the model made from features to the target, and that it had understood from the data. It also shows if this relation is linear or not, monotonic or not, ... Partial dependence plots were first introduced in Friedman (2001) and are also well described in Molnar (2020). Briefly, partial dependence plots for a feature of interest is obtained by marginalizing the predicted output over the values of all other input features. This marginalization is done by calculating averages in the training data, using a Monte-Carlo method, with a fixed value for the features of interest.

An important limitation of partial dependence plot is that their methodology of construction assumes independence between the features, which does not seem to be the case for ESG features. This limitation is neglected here. All partial dependence plots are made with the most recent model, trained with data from 2002 to 2019, on a subsample of recent ESG data.

5.2.2 Marginal effect of the ESG features

Using partial dependence plots, we first plot the marginal effect of each ESG feature on the probability of having a positive return during the year of publication of the ESG features. These plots are shown in Fig. 11. Figure 12 shows the impact of belonging to one sector or the other on the probability of having a positive return.

Figure 11 shows that ESG features are mostly not related in a monotonic way with the probability of having a positive return. A clear exception would be the Controversy score, on the top left, which shows a strong monotonic relation with a clear idea that being subject to controversies during a year leads to a lower probability of having a positive return. For the 10 pillar scores, even if some features show some effect, most effects remain small. For example, the probabilities of positive price return increases by around 1% when the Product Responsibility and Shareholders scores increase from 0 to 1. Still, a trend remains observable for most of these ESG features: partial dependence plots for features such as Resource Use, Innovation, Community or Management seems to be decreasing, suggesting that having and working towards better ESG scores and practices would come at the price of financial performance.

5.2.3 Marginal effect of the ESG features sector by sector: materiality matrices

Adding the dimension of sector to partial dependence plot yields so-called materiality matrices. In our setting, it is a table whose rows represent EGS features and whose columns are economic sectors. A cell of this matrix shows, in percentage, by how much the probability of having a positive return is increased by going from a low score (between 0 and 0.2) to a high one (by 0.8 to 1). This quantity is easily obtained using partial dependence plots: for a specific selected economic sector, we can plot the evolution of the predicted probability against the feature value. Making the strong hypothesis of a monotonic and close to linear relationship, we can compute the value in the cell as the slope of the trend line of the precedent plot.

The obtained materiality matrix is presented in Fig. 13. All sectors according to the Thomson Reuters classification at level 1 are presented. Results for the Academic & Educational Services should be handled with care as they are not based on as many samples as the ones for other sectors, as shown in Fig. 1. Some ESG scores have some strong impact on the probability of having positive returns. The Controversy score especially has a similar impact for all sectors: not suffering controversies during
Figure 11: Marginal effect of each ESG feature on the predicted probability of having a positive return.
the year increases the probability of having a positive return. On the contrary, the CSR Strategy row shows that working towards the integration of social and environmental dimensions into the day-to-day decision-making processes, in addition to economic and financial ones, leads to a loss of financial performance. It is also the case for the Resource Use, environmental Innovation, Community or Management scores, with different magnitude according to the sector.

Going further, we can bucket the companies which serve to build this materiality matrix by market capitalization. We choose three buckets, with small market capitalization being below 2 billion euros, mid ones between 2 and 10 billion euros and large ones above 10 billion euros. These buckets are the same Refinitiv uses when calculating the Controversy score. The three obtained materiality matrices are presented in Fig. [14]. The marginal effect of the Controversy score remains the same, even if it is a bit lower for the small caps. However, companies with a large market capitalization benefit from a better impact of ESG: for some features, working toward better ESG scores can preserve or even boost financial performance, whereas it would be the opposite for small caps. For instance, large caps companies have a average materiality of 0.8 for the Resource Use score and 1.5 for the Emissions scores, whereas small caps ones have respectively average scores of -4.6 and -1.1, denoting a clear difference.

To obtain a statistically meaningful interpretation of these results, we need to account for the fact that to each cell corresponds coefficients of a linear fit with associated p-values, i.e., one makes one null hypothesis per cell. We thus need to use multiple hypothesis correction to check globally which cell are statistically significant results. Here, we choose to control the False Discovery Rate with the Benjamini–Hochberg procedure [Benjamini and Hochberg [1995]]. We set the FDR to 5%, which means that there are only about 3 false discoveries in each of the reported tables.
Figure 13: Materiality matrix: marginal effects of the combination ESG feature/Sector feature on the predicted probability of having a positive return. Blank cells are those which were not found statistically significant by the Benjamini–Hochberg procedure.
Figure 14: Materiality matrices: marginal effects of the combination ESG feature/Sector feature on the predicted probability of having a positive return, bucketed by market capitalization. Blank cells are those which were not found statistically significant by the Benjamini–Hochberg procedure.
6 Conclusion

While ESG data are not yet fully mature and lack long enough quality records to be amenable to easy conclusions, powerful machine learning and validation techniques make it already possible to show that they do influence yearly price returns, and increasingly so. We stress that our results are specific to the Refinitiv ESG dataset. Breaking down their influence sector by sector, subscore-wise and according to market capitalization clearly demonstrates that an average approach will fail to be informative. We found in particular that the relationship between controversies and price return is the most robust one. The average influence of all the other ESG scores depends much on the capitalization of a company: strikingly, most of the statistically significantly influential ESG scores weigh negatively on price returns of small or mid-size companies. Large-capitalization companies on the other hand have significantly advantageous ESG score types.

While this work proposes a methodology suitable to an explanatory persuit, our methodology can be used to explore the predictive power of ESG data provided that data revision is under control.

While this work focuses on explaining the idiosyncratic part of price returns derived from the CAPM model, those derived from the Fama-French 3-factor model lead to results that are less clear cut for the time being. Indeed, they seem to contain promises: the correlations between validation and test set increased in 2018 and 2019 and thus ESG data seem to become more informative. Future work will focus on the study of the full 2020 and 2021 years to check if the dynamic is confirmed.

Future work will also include studying outliers of the SHAP values distribution and verifying the hypothesis that extreme scores in the ESG field are more informative. In addition, the link between ESG and equity returns is complete only if the systematic and idiosyncratic aspects of risks and returns are studied together (Giese and Lee 2019): indeed, it may be that having better ESG scores not only decreases price returns but also risk.

This work originates from a partnership between CentraleSupélec and BNP Paribas.

A 10 Pillar Scores

Environmental scores

- Resource Use: Reduce the use of natural resources and find more eco-efficient solutions by improving supply chain management.
- Emissions: Commitment and effectiveness towards reducing environmental emissions in the production and operational processes.
- Innovation: Reduce the environmental costs for customers, and thereby creating new market opportunities through new environmental technologies and processes or eco-designed products.

Social scores

- Workforce: Job satisfaction, healthy and safe workplace, maintaining diversity and equal opportunities, development opportunities for workforce.
- Human Rights: Respecting the fundamental human rights conventions.
- Community: Commitment towards being a good citizen, protecting public health and respecting business ethics.
- Product Responsibility: Producing quality goods and services integrating the customer's health and safety, integrity and data privacy.

Governance scores

- Management: Commitment and effectiveness towards following best practice corporate governance principles. Composition, remuneration, transparency of the board.
- Shareholders: Equal treatment of shareholders, use of anti-takeover devices.
- CSR Strategy: Integration of social and environmental dimensions into the day-to-day decision-making processes, in addition to economic and financial ones.

B Results with the target derived from the Fama-French 3-factor model

The following results were obtained with a target derived from the Fama-French 3-factor model as exposed in 3.1. This target was not selected as results were not as good as those obtained with the target derived from the CAPM model. How to interpret results with this target, especially in terms of materiality matrices, was also less clear. For the interested reader, we present our results, using a 5-fold company-wise splitting strategy, in Tab. 3 and 4. Display of the relationship between $L_{\text{test}}$ versus $L_{\text{validation}}$ for each model $m$ ranking in the top 100 validation cross-entropy losses are shown in Fig. 15.
Figure 15: Company-wise cross-validation: test set cross-entropy versus validation cross-entropy of the 100 best models of the random hyperparameters search, for a target computed using the Fama-French 3-factor model.

Table 3: Dependence measures between the cross-entropy losses in the validation and test sets, for the 100 best models of the random hyperparameters search, for a target computed using the Fama-French 3-factor model.
### Company-wise 5-fold cross-validation

| Year | Balanced Accuracy | Cross-entropy loss | Balanced Accuracy | Cross-entropy loss |
|------|-------------------|--------------------|-------------------|--------------------|
| 2016 | 57.9              | 65.8               | 56.0              | 66.7               |
| 2017 | 55.0              | 70.6               | 55.2              | 71.6               |
| 2018 | 56.0              | 70.4               | 56.0              | 71.1               |
| 2019 | 62.4              | 64.6               | 64.7              | 64.1               |
| 2020 | 56.1              | 72.2               | 55.3              | 71.3               |

Table 4: Performance measures on the test set, for a target computed using the Fama-French 3-factor model.

C  Relationship between validation and test cross-entropy losses for the temporal train/validation scheme
| Year | Test LogLoss |
|------|--------------|
| 2016 | 0.676 0.678 0.680 0.682 0.684 |
| 2017 | 0.672 0.674 0.676 0.678 0.680 |
| 2018 | 0.674 0.676 0.678 0.680 0.682 |
| 2019 | 0.668 0.670 0.672 0.674 0.676 0.678 0.680 |
| 2020 | 0.665 0.6675 0.670 0.6725 0.675 0.6775 |
