Abstract The univentricular heart after the Fontan operation may have a blind pouch formed by the pulmonary stump or rudimentary ventricle according to the anatomy before surgery. Thrombosis in an intracardiac blind pouch of patients with a univentricular heart is a hazardous complication. Because only a few reports have described this complication, the authors evaluated the clinical significance of thrombosis in an intracardiac blind pouch of a univentricular heart. They performed a retrospective review of medical records from August 1986 to December 2007. Four patients were confirmed as having thrombosis in a pulmonary artery stump and one patient as having thrombosis in a rudimentary ventricle shown by cardiac computed tomography (CT). This represents 1.85% (5/271) of patients with ongoing regular follow-up evaluation after the Fontan operation. The median age at diagnosis was 14.2 years. Two of the five patients were taking aspirin and one patient was taking warfarin when they were identified for the development of thrombosis. None of the patients demonstrated thrombosis in the Fontan tract or venous side of the circulation. Brain magnetic resonance imaging (MRI) showed that three patients had cerebral infarction and one patient had suggestive old ischemia. Three patients with thrombus in the pulmonary stump underwent pulmonary artery stump thrombectomy and pulmonary valve obliteration. One patient with thrombus in the rudimentary ventricle underwent ventricular septal defect (VSD) closure with thrombectomy. Thrombus in a blind pouch could cause systemic thromboembolism despite little blood communication. Therefore, surgical modification of the pulmonary stump and VSD closure of the rudimentary ventricle are required to reduce the risk of later thrombus formation. Clinicians should not overlook the possibility of thrombus in a ligated pulmonary artery stump or a rudimentary ventricle after the Fontan operation, which may increase the risk of embolic stroke for patients with single-ventricle physiology.

Keywords Echocardiography · Fontan · Stroke · Thrombosis

Since its initial introduction in 1971, the Fontan procedure has undergone multiple modifications [6, 19] aimed at directing the systemic venous return directly to the pulmonary artery (PA) [10]. Subsequently, in several cases, various surgical mortality rates associated with diverse approaches have been reported [1, 11, 15, 16].

Fontan physiology has been called paradoxical because systemic venous hypertension is imposed with concomitant PA hypotension [5]. This hemodynamic compromise underlies several late complications including arrhythmia, heart failure, thromboembolism, hepatic dysfunction, protein-losing enteropathy, and worsening cyanosis [12, 13].

Among these complications, intracardiac thrombus formation is serious and can be fatal because of thromboembolism to vital distal organs. Although thrombosis has been reported to occur in a variety of locations [4, 24], few reports describe thrombosis in an intracardiac blind pouch,
including a ligated main pulmonary stump or a rudimentary
ventricle, and its risk for cerebrovascular embolic events.

Recently, we experienced several cases of thrombosis in
an intracardiac blind pouch, resulting in thrombectomy.
This study aimed to evaluate the clinical significance of
thrombosis in an intracardiac blind pouch after the Fontan
operation on a univentricular heart.

Materials and Methods

We retrospectively reviewed the medical records of all
patients who had undergone the Fontan operation with
ongoing follow-up evaluation from August 1986 to
December 2007 at the Seoul National University Children’s
Hospital. At our institution, all the patients who under-
went palliated single-ventricle physiology were routinely
screened by transthoracic echocardiography (TTE) for
thrombosis in the systemic circulation, including a ligated
main pulmonary stump or a rudimentary ventricle. The TTE
was performed with the Acuson Sequoia C256 (Siemens
Company, Mountain View, CA, USA) or the GE Vivid 7
scanner (GE Vingmed Ultrasound, Horten, Norway) used by
an experienced pediatric cardiologist according to a stan-
dardized protocol. This study protocol was approved by our
Institutional Review Board, which waived the patient con-
sent because of the retrospective data analysis.

Cardiac computed tomography (CT) was performed for
142 of 271 patients with ongoing follow-up evaluation
after the Fontan operation to assess for cardiac, pulmonary,
hepatic, or other complications. Because CT imaging is
useful for identifying structural anomalies or relations, it
was performed for patients with suspected pulmonary
arterial anomalies, intracardiac thrombus as noted by
echocardiography, airway problems such as plastic bron-
chitis, and liver mass or cirrhosis. On the other hand, CT
was not performed routinely for all Fontan patients.

The study acquired CT data using a multidetector CT
scanner (Sensation 64; Siemens Medical Systems,
Forchheim, Germany) with a 32-row detector collimation
that obtained 64 x 0.6-mm slices by applying the z-axis
flying-focus technique, a table translations speed of
3.8 mm per rotation, and a gantry rotation time of 0.33 s.
In all patients, nonionic contrast medium (Ultravist;
Schering, Erlangen, Germany) was injected for vascular
enhancement. A thrombus was defined as a “hypodense”
lesion. The CT density (in Hounsfield Units) was measured
within multiple regions of interest (ROIs) on axial images.

We identified five patients with thrombi in an intracar-
diac blind pouch after a Fontan operation. We also per-
formed brain magnetic resonance imaging (MRI) if the
patients showed neurologic symptoms such as periodic
headache, behavioral change, seizure, sensory change, or
motor weakness. An MRI was acquired for all patients with
identified thrombi using a circularly polarized head coil
in a conventional 1.5-T whole-body imaging system
(Magnetom Vision, Siemens Medical Systems, Iselin, NJ).
In addition, we reviewed medical records concerning the
first palliative operation, types of Fontan operation, age at
the time of diagnosis, methods of antithrombotic medica-
tion, presence of neurologic complications, treatment
methods, and final outcomes for thrombosis.

Results

Patient Characteristics

The clinical characteristics of the patients are described in
Table 1. For five patients, thrombi in an intracardiac blind
pouch was identified by TTE and cardiac CT. This com-
prised 1.85% (5/271) of the patients with ongoing regular
follow-up evaluation after a Fontan operation. All the
patients were male. The median age of the patients at the
time of this study was 17.2 years (range, 7.0–17.8 years),
and the median age at the diagnosis of thrombus in the
systemic circulation was 14.2 years (range, 0.6–15.4
years). Four of the five patients experienced thrombi in the

### Table 1 Clinical characteristics of the patients

PA pulmonary artery; Dx diagnosis; MRI magnetic resonance imaging; PAB pulmonary artery banding; ECC extracardiac conduit; RMBTS right modified Blalock-Taussig shunt; LT lateral tunnel; BCPS bidirectional cavopulmonary shunt
ligated main PA stump. The remaining patient had a thrombus in the rudimentary ventricle (Fig. 1).

As a first palliative operation, two patients underwent PA banding. One patient received a Blalock-Taussig shunt, and two patients received a bidirectional cavopulmonary shunt. Fontan operations were performed at a median age of 2.84 years (range, 1.1–3.75 years). Among the types of Fontan operation, two patients had surgery using an extracardiac conduit, and three patients underwent surgery by the lateral tunnel method. Before the diagnosis of thrombus, two patients had taken aspirin, one patient had taken warfarin, and two patients had not have taken any antithrombotic medication. Two patients had mild liver cirrhosis shown by abdomen CT but did not have significant coagulopathy. Therefore, no patient had protein S or C deficiency.

Neurologic Complications and Treatments

Four patients showed brain infarct or ischemia on brain MRI. Three of the four patients had neurologic symptoms including seizure and right-side palsy in patient 2, left hemiparesis in patient 3, and syncope in patient 5 (Table 1).

Patient 2, who had tricuspid atresia type 1b, underwent a fenestrated lateral tunnel Fontan operation at the age of 3 years. At 2 years after PA ligation, the patient experienced partial seizure and right-side palsy, which resolved after anticoagulation treatment. Partial seizure developed subsequently and occurred three additional times.

When the patient was 16 years old, routine TTE showed thrombus in the ligated main PA stump, which was confirmed by cardiac CT. Brain MRI showed multifocal T2 high-signal intensity nodules in the left thalamus and periventricular white matter and cerebellum, which represented old cerebral infarctions due to thromboembolism (Fig. 2a).

Although we did not know whether the cause of recurrent neurologic complication was fenestration of the Fontan pathway or not, the blind pouch of the main PA stump could have been a nest of thrombus formation. The patient underwent thrombectomy in the main PA stump and pulmonary valve obliteration. At this writing, he is receiving warfarin as an antithrombotic agent after thrombectomy.

Patient 3, who had a double-outlet right ventricle and double-inlet right ventricle, underwent the Fontan operation with an extracardiac conduit at the age of 32 months. At the age of 30 months, the patient experienced right-side lip deviation and left-side weakness in the extremities. Brain MRI showed an acute infarction in the right middle cerebral artery territory (Fig. 2b). All symptoms resolved with subcutaneous injection of low-molecular-weight heparin and subsequent warfarin medication. However, cardiac CT identified thrombus in the main PA stump at the time of treatment that was not seen at the time of the Fontan operation.

Patient 4, who had an unbalanced atrioventricular septal defect with pulmonary stenosis, underwent a lateral tunnel Fontan operation at the age of 4 years. Routine TTE showed thrombus in the ligated main PA stump when the patient was 14 years old, which was confirmed by cardiac CT. The patient did not show any neurologic symptoms, but brain MRI showed a few T2 high-signal lesions in both paraventricular white matters reflecting old cerebral infarctions (Fig. 2c). Although he did not have any neurologic symptoms, we performed thrombectomy in the main PA stump and pulmonary valve obliteration because of blood flow communication through the pulmonary valve and concern about systemic embolization from a thrombus in the PA stump. At this writing, he is receiving aspirin as an antithrombotic agent.
Patient 5, who had a double-outlet right ventricle with a hypoplastic left ventricle (LV), underwent a lateral tunnel Fontan operation at the age of 3 years. At the age of 7 years, he experienced syncope, motor weakness, and vomiting. Brain MRI showed a cerebral infarction in the temporo-occipital area (Fig. 2d), and a thrombus in a rudimentary LV was identified on TTE. All symptoms and thrombus disappeared after anticoagulation therapy. However, routine TTE at the age of 15 years showed the reappearance of thrombotic materials in the rudimentary LV, and a cardiac CT confirmed the thrombus in the rudimentary LV (Fig. 1b). This occurred despite continuous medication with warfarin. Closure of the residual ventricular septal defect (VSD) and thrombectomy were performed.

Discrepancy in the Diagnosis of Thrombus Between Cardiac CT and TTE

Three patients in our study showed thrombi in the main PA stump and a rudimentary ventricle on the cardiac CT performed for atypical symptoms and pulmonary problems. However, we could not visualize thrombus by repeat TTE. For one of them, TTE and LV angiography by contrast-media injection were performed, but we could not identify a significant thrombus in the systemic circulation, in contrast to the cardiac CT (Fig. 3). We did not perform any treatment for the thrombus shadow in the cardiac CT because the patients did not exhibit any neurologic symptoms, and repeated TTE did not show a thrombotic shadow at all. At this writing, the patients all are being closely followed.

Discussion

Many complications may occur late after the Fontan procedure including thromboembolism, heart failure, sepsis, and other problems [12, 18, 26]. Thrombus formation is considered a significant cause for morbidity and mortality [4, 12]. Thromboembolism after a Fontan operation has been variously attributed to low flow states, stasis in the venous pathways, right-to-left shunts, blind cul-de-sacs, prosthetic materials, atrial arrhythmias, and hypercoagulable states [2, 12, 25].
Intracardiac thrombus formation can lead to pulmonary thromboembolic disease if it occurs within the Fontan circuit, whereas cerebral stroke and infarct develop if the former type of thrombus crosses a Fontan fenestration or if the thrombus forms within left heart structures [4]. Left-sided embolism could lead to neurologic deficit, organ dysfunction, or death [7]. Therefore, thrombus in the systemic circulation (left-sided embolism) is a more serious condition that should be treated urgently. Three of the five patients in this study had neurologic complications that required an immediate response.

Several studies have reported the prevalence of intracardiac thrombus development to be 3–33% [4, 13, 22, 24]. In many studies, the predisposing factors for intracardiac thrombosis included hepatic dysfunction, protein-losing enteropathy, and arrhythmia. Generally, patients after the Fontan operation show a hypercoagulable state caused by deficiencies in protein S, protein C, factor 7, and anti-thrombin 3. Deficiencies of coagulation factor may relate to decreased hepatic function and enteric losses.

In 2001, Coon et al. [4] reported that the curve of thrombus formation very closely mimics the previously published curves for the development of arrhythmia and protein-losing enteropathy after a Fontan operation [3, 8]. These findings suggest the co-dependent relation between thrombus formation and other late complications.

Thrombosis in the systemic circulation of the univentricular heart has not been reported frequently [17, 20, 21, 27]. Formation of a blind pouch after the Fontan operation in patients with single-ventricle physiology is not unusual. Flow patterns suggest that there is some inflow to the cul-de-sac and that small regurgitated jets emanating from the valve leaflets may be observed. Because the only outlet from these hearts is the aorta, the thrombus will enter the systemic circulation if it dislodges. Another cul-de-sac in patients who undergo the Fontan operation is a rudimentary ventricle, in which a thrombus could be formed.

There are surgical methods for decreasing the risk of embolic events. One method is an excision of the pulmonary valve leaflets at the time of the bidirectional cavopulmonary shunt or Fontan procedure, when the PA is ligated. With this approach, the proximal stump widely communicates with the ventricular chamber without stasis of blood.

Another approach involves oversewing of the leaflets, which eliminates the communication between the proximal PA stump and the systemic ventricle. However, oversewing of valve leaflets in an infant with more delicate valve tissue may not be feasible. Also, for prevention of thrombosis in the rudimentary ventricle, widening or closure of communication between the main and rudimentary ventricle is required when the bidirectional cavopulmonary shunt or the Fontan procedure is performed. Then, the rudimentary ventricle must be followed carefully by routine echocardiography.

Because thrombus formation in patients after the Fontan operation is a major complication, accurate diagnosis of the thrombosis by means of an imaging study is the first step for optimal treatment. In clinical practice, echocardiography for the diagnosis of intracardiac thrombus has a low sensitivity and a high specificity [23]. Generally, TTE has an overall sensitivity of 20–30% and a specificity exceeding 95%, whereas transesophageal echocardiography has an overall sensitivity of 30–40% and a specificity exceeding 95%. On the other hand, cardiac CT has high sensitivity and specificity and a low positive predictive value [9]. Generally, the positive predictive value of cardiac CT for intracardiac thrombus is less than 40%.

These false-positive findings may be explained by spontaneous sluggish echo contrasts in Fontan patients. Early CT data acquisition during the arterial phase and
filling defects in cul-de-sacs could be causes of a misdiagnosed thrombosis in the atrial appendage, pulmonary stump, or rudimentary ventricle [14]. In this regard, for three other patients in our study, thrombus of the systemic circulation was diagnosed based on false-positive results from cardiac CT. The positive findings from cardiac CT that do not meet clinical conditions must be evaluated by another diagnostic method.

Differentiating the thrombus from a fibrosis or scar can be quite challenging with echocardiography and cardiac CT. Cardiac MRI, by using delayed enhancement imaging, may help to diagnose thrombus formation better in such patients.

How to protect patients from the occurrence of thrombosis after the Fontan operation remains unclear, particularly considering our findings of thrombus formation even in patients receiving aspirin or warfarin. Therefore, prospective trials to determine the potential benefits or risks of routine anticoagulation for all children after the Fontan operation are warranted.

In conclusion, we should not overlook the possibility of thrombus in a ligated PA stump or a rudimentary ventricle after the Fontan operation, which may increase the risk of embolic stroke in patients with a single-ventricle physiology. Empirical modifications of the PA stump and rudimentary ventricle to reduce the risk of later thrombus formation must be attempted. Aggressive thrombectomy for patients with thrombosis of the proximal PA stump and rudimentary ventricle should be considered to prevent neurologic complications. Thrombi identified by cardiac CT should be considered carefully in the diagnosis and treatment due to the low predictive rate.
