Abstract

Expanded polystyrene is widely used as a material for packaging, in modern construction as a heat and sound insulation layer, in thermal insulation systems for buildings, as well as tanks and pipelines. It is additionally used in foundry engineering for the production of models which are gasified during the production of castings from ferrous and non-ferrous alloys under the contact with liquid metal. The use of expanded polystyrene products is associated with waste generation, both in production and in consumption. About 40–50 kg/person of polystyrene waste is generated per year. The peculiarity of polymeric wastes is their resistance to aggressive environments. They do not rot and the destruction processes in natural conditions proceed rather slowly, with the formation of harmful substances that poison the environment. Therefore, the problem of the processing of waste from polymeric materials is of great importance, not only from the standpoint of environmental protection, but also due to the fact that in conditions of a shortage of polymeric raw materials, this waste becomes a powerful raw material resource. This article describes the prospects for recycling expanded polystyrene wastes in foundry engineering. In this work, the properties of molding and core mixtures containing a solution of polystyrene waste in turpentine as a component are investigated, and their main characteristics (weight during stretching and crumbling) were determined. Molding and core mixtures, which contain only a binder in the form of a solution of expanded polystyrene in turpentine, have a crude strength of not more than 0.01 MPa. The introduction of a mixture of clay in the amount of 2–3% allows a crude strength of the mixture of up to 0.05 MPa to be obtained. After drying, the investigated mixtures containing a solution of expanded polystyrene wastes and clay have a tensile strength of up to 2.1 MPa. Mixtures into which a solution of polystyrene wastes and clay was introduced have an insignificant gas capacity and satisfactory gas permeability.

Keywords: waste, solution, polystyrene, turpentine, strength limit, sprinkling, residual strength

1. INTRODUCTION

The use of products made of polymeric materials is inextricably linked with the generation of wastes, both in the field of production and in the field of consumption. The peculiarity of polymer waste is their resistance to aggressive environments. Such materials simply do not rot. The processes of their destruction in natural conditions are quite slow, with the formation of harmful substances that poison the environment. In 2016, the global production of polystyrene and expanded polystyrene (EPS) was around 14.7 and 6.6 million metric tons per annum [1].

The problem of processing and recycling polymeric waste is currently of great importance, not only from the standpoint of environmental protection but also due to the fact that in conditions of shortage of polymeric raw materials, such wastes become a powerful raw material resource.

The properties of sand-clay molding mixtures containing a solution of polystyrene waste in turpentine as a component are the object of the study. The aim of this study is to improve the properties of sand-clay molding and core mixtures by using a solution of EPS in turpentine as a binder.

2. USE OF EXPANDED POLYSTYRENE AND THE FORMATION OF ITS WASTE

EPS can be found in many areas of modern life. EPS is widely used as a material for food packaging and storage. This fact emphasizes the hygienic properties of EPS, the properties of which do not change over time. EPS packaging often contains...
meat, fish, frozen or fresh vegetables, and beverages. Almost all packaging for household electronics is currently made of EPS. It is widely used in modern construction as a heat and sound insulation layer in systems of warming of houses and other buildings, and also capacitive devices and pipelines [2–5]. EPS is also used in foundry engineering to obtain models under gasification in contact with liquid metal in the production of castings from ferrous and nonferrous alloys [6–10]. Up to 10% of raw materials goes to waste during the production of gasified models by the method of thermoplotter cutting of polystyrene block [11].

3. RE-USING OF EPS WASTE

EPS packaging accounts for 40% of all household waste and does not decompose. Therefore, the use of such packaging is associated with the generation of waste totaling approximately 40–50 kg/year per person [11]. EPS wastes do not decompose during deposition in landfills and cause great damage to the soil. An alternative method is incineration. However, compounds are released during combustion which cause acid rain and is detrimental to the environment. Ash is also formed during combustion which is easily sprayed with air over a large area. Such ash causes great harm when inhaled, leading to pulmonary poisoning and irritation.

Generally, re-using, mechanical recycling, chemical recycling, and energy recovery have been the four main options conventionally-used for the reclamation and recycling of plastics. EPS contains more than 98% of air; making its recycling uneconomical and inexpedient [12].

These are the following priority areas for the re-use of EPS waste [13–17]:

- polystyrene coating for waterproofing,
- protective and decorative polystyrene coverings,
- polystyrene coatings for pottery,
- paints and varnishes for painting,
- thermocompaction of polystyrene waste,
- composite materials with expanded polystyrene matrix,
- binder component for molding and rod mixtures.

It should be noted that molding and rod mixtures based on the binder have easy knockout and high strength [18–23]. EPS wastes are mainly used in foundry engineering as a component for molding and core mixtures in the form of solutions at the metallurgical enterprises of Ukraine and nearby countries.

The preparation of solutions of EPS in organic solvents is due to a multiple decrease in the initial volume of expanded polystyrene and a significant increase in the volume of the solution compared to the volume of the solvent. Therefore, the preparation of polystyrene solutions is a convenient way to compact it. The most commonly used solvent for polystyrene wastes is gum turpentine [24]. Turpentine dissolves polystyrene wastes well and has low volatility.

As a result of a number of studies [20–23], the technology of EPS recycling was created. It is possible to make modern, low-toxic binding materials for the production of sand molding and core mixes, and also coverings of molds using EPS wastes. It makes it possible to improve and develop new, more efficient and cost-effective metal casting processes. In addition, the use of EPS wastes is of great environmental importance, as it is about reducing the amount of such wastes in landfills [25–29].

If the low volatility of gum turpentine is a positive factor from the point of view of the requirements of sanitary working conditions, it is negative from the perspective that there is a technological need to ensure the accelerated hardening of forms and cores, since this demands the compulsory removal of any solvent from mix. There are a number of ways to remove the liquid composition from the mixture, including vacuuming and blowing the mixture with dry heated air. The temperature exposure during drying in ovens is the most affordable method [26–28]. Analyzing the use of an EPS solution as a binder for molding and core mixtures, a number of problems can be identified that are associated with the implementation of this scheme into production. The most significant problem is technical. The use of binder in a "pure" form provides a raw strength of mixtures of no more than 0.01 MPa. It is known that if the strength of mixtures in the raw state is very low – less than 0.01 MPa, it requires the use of additional special equipment-drivers, equipment necessary to move the manufactured product to the driver subsequent transportation and heat treatment to obtain the required technological strength, which increases the cost of production as well as lengthening the technological cycle of manufacturing casting. The solution to this problem may be the application of a combined binder containing additional liquid glass or clay to the EPS solution [27–30].

4. MATERIALS AND METHODS

In this study, research was carried out by dissolving EPS waste PSBS-25 in turpentine (Technical Specification No. 24.3-30959 201-001-2004). The choice of PSBS-25 samples is justified by the fact that it is used in the manufacture of models for Lost Foam technology by means of thermoplotter cutting. PSPB-25 is the most common type of expanded polystyrene due to its low density, and therefore a low ash residue after combustion and low carburization of steel. 30% of the used polystyrene foam is scraped off. Therefore, disposal of polystyrene foam wastes is an urgent problem. Dissolving them with turpentine is a regulated and environmentally friendly process. Turpentine vapors are environmentally neutral, unlike nitro solvents.

The quartz sand grade K2 was used as a grain base for the preparation of mixtures. A clay from deposit of Chasiv Yar was used as a binder in the form of a dry powder.

The mixture was prepared in a paddle mixer. First, the dry components were mixed for 5 minutes, and then a solution of foam plastic in turpentine was added and mixed for 10 minutes.

Standard test samples were made using the 2M030 laboratory device for the production of standard samples of foundry mixture. Drying of the samples was performed in a chamber dryer model for 1 hour at a temperature of 150°C. Compression and tensile tests were performed on standard samples on a universal model device 5070A. Determination...
of gas permeability was carried out using the accelerated method DSTU 29234.11-91 by passing room temperature air through a standard sample of the test material on the model device 042-M. The gas-forming capacity of the mixture was determined in accordance with GOST 23409.12-78 – "Molding and rod mixtures. Method for determining gas solubility".

Scattering was determined on standard samples according to DSTU 23409.9-78: in 10 minutes after preparation of mixtures and production of samples, in an hour, in 3 hours and after 24 hours. Residual strength was determined by heat shock in the temperature range 150–800°C.

The hygroscopicity of the samples was determined according to GOST 23409.10-78.

5. RESULTS AND DISCUSSION

5.1. Dissolution of EPS in turpentine

It is known from the literature [17–20] that the best strength properties of foundry mixtures are given by 38–40% solution of EPS in turpentine.

Preparation of such a solution from EPS waste in turpentine showed the first positive result of the study on their utilization, namely that there is a sharp decrease in the volume of waste.

Figure 1 shows the volume of 40 grams of EPS waste and the volume of the solution obtained after dissolution to obtain the desired 40% concentration (ingredients ratio EPS/turpentine = 40 g/60 g).

5.2. Investigation of the properties of molding mixtures containing EPS wastes and clay as a binder

In this study, the possibility was investigated of obtaining molding of a sufficient raw strength by introducing small additives of molding clay mixtures with a binder solution of EPS waste in turpentine.

In the preparation of mixtures, 1.5, 2.0 and 3.0% clay was administered. Figure 2 shows the effect of clay content on the raw compressive strength, and Figure 3 on the dry tensile strength of mixtures.

From the figures it is visible that the introduction of clay in the investigated mix allows us to obtain a crude durability of more than 0.01 MPa. So, the possibility of manipulation of cores without additional technological operations and special equipment is provided. Increasing the clay content from 1.5% to 3.0% leads to an increase in the raw compressive strength of the samples from 0.01 MPa to 0.05 MPa. At the same time, the tensile strength of dry samples increases insignificantly from 2.07 MPa to 2.10 MPa.
Residual strength was determined on samples of a mixture containing 3% clay, after heating to 150, 200, 250, 300 and 400°C. The test results of the samples under compression are shown in Figure 4.

The compressive strength of this mixture after exposure to 150°C for 1 hour exceeds 3 MPa.

The curve in Figure 4 shows that the investigated mixture begins to lose strength intensively at 250°C ($\sigma = 0.3$ MPa). Presumably this is due to the thermal destruction of the polystyrene film that binds the grains of sand. After heating to 300°C, the mixture significantly loses strength ($\sigma = 0.08$ MPa), and after heating to 400°C, the samples were destroyed in the furnace.

5.3. Investigation of the effect of small impurities of EPS solution in turpentine on the properties of standard sand-clay mixtures

The study was performed on a sand-clay mixture containing 10% clay as a binder. Additionally, a 40% solution of EPS in turpentine was introduced into the mixture (this corresponded to 0.4% in terms of polystyrene). Samples of the control mixture that did not contain polystyrene were examined at the same time. The bulkiness and residual strength (which characterizes the knockout) of mixtures were investigated.

The bulk (surface strength) characterizes the ability of a mold or rod to maintain its configuration under the influence of a jet of liquid metal, as well as other forces that occur, for example, during transportation or assembly of the mold. One way to reduce the scattering is to increase the clay content in the mixture. The inevitable consequence of increasing the clay content in the mixture is a deterioration of its knockout and pliability, which is undesirable.

The aim of this stage of the study was to use small impurities of a solution of expanded polystyrene in turpentine to obtain a sand-clay mixture with high scattering rates and low residual strength.

Figure 5 in semi-logarithmic coordinates shows a graph of the change in the scattering of the control and experimental mixture over time. During the experiments, it was observed that the samples from the test mixture had a scatter less than the control in all cases.

The figure shows that after exposure for 1 hour, the scattering of both mixtures increases slightly, after 3 hours decreases significantly and, after 24 hours, grows again.

Figure 6 shows the dependence of the residual strength of the test mixture in comparison with the control from the heating temperature of the samples.

Figure 6 shows that the mixture has greater tensile strength than the control in the initial state of the test. That is, the admixture of expanded polystyrene solution acts as a strengthening component.

It was found that at heating temperatures < 600°C, the test specimens also had a residual strength greater by 15–20%
than the control ones. This is most likely due to the incomplete destruction of the polystyrene molecules. The completion of this process at a higher temperatures (600–800°C) provided a decrease in the compressive strength of the experimental samples in comparison with the control by 10–12% (Fig. 6), so the mixture of these samples had better knock-out. Analysis of Figure 6 shows that a small amount of EPS waste acts as a strengthening and softening component of the sand-clay mixture.

6. CONCLUSIONS

A large amount of waste is generated under the production and consumption of expanded polystyrene. Possessing chemical inertness, this waste accumulates in the environment and harms it. Expanded polystyrene wastes can be used as a raw material for the production of waterproofing, protective and decorative coatings for wood and pottery, paints and varnishes for painting, the basis of composite materials, a binder component for molding and core mixtures in foundry production.

Based on the research, it was found that:

1. Molding and core mixtures containing only a binder in the form of an EPS solution in turpentine, have a raw strength of not more than 0.01 MPa.
2. The introduction of clay into the mixture in the amount of 2.0–3.0% allows us to obtain a crude strength of the mixture of up to 0.05 MPa.
3. After drying, the test mixtures, in which a solution of EPS waste and clay was introduced, have a tensile strength from 2.07 MPa to 2.10 MPa.
4. Mixtures with the EP Swaste solution and clay have insignificant gas capacity and satisfactory gas permeability.
5. The study of the effect of small impurities of the EPS solution on the mixture of the properties of sand-clay mixtures have revealed that the studied mixtures (in comparison with the control) have less scattering and residual strength.
