(Received 29 January 2018; published 20 September 2018)

Simple models of single-field inflation in the very early universe can generate the observed amplitude and scale dependence of the primordial density perturbation, but models with multiple fields can provide an equally good fit to current data. We show how future observations will be able to distinguish between currently favored models. If a curvaton field generates the primordial perturbations after inflation, we show how the total duration of inflation can be measured.

DOI: 10.1103/PhysRevD.98.063525

I. INTRODUCTION

In the standard cosmological model, all structures in our Universe originate from quantum vacuum fluctuations [1–6] during an early phase of accelerated expansion [7–12]. With the advent of high-precision measurements [13,14] of the temperature and polarization anisotropies of the cosmic microwave background (CMB), we can place tight constraints on this primordial epoch called inflation. At a given physical length scale, the statistical properties of cosmological fluctuations are mostly determined by the details of the classical inflationary dynamics around the time when this scale crosses the Hubble radius during inflation. The range of scales probed in the CMB then translates into a time interval during inflation of length \( \Delta N \sim 7 \), measured by the number of e-folds, \( N_1 - N_0 = \ln(a_1/a_0) \), where \( a \) is the scale factor of the Universe. If one includes measurements of the large-scale structure (LSS) of our Universe, this window is extended, but cannot exceed the last \( \sim 60 \) e-folds of inflation.

Besides this lower bound (whose precise value depends on the reheating expansion history [15–21]), the overall duration of inflation is not known.

One way to circumvent this cosmic amnesia and to learn about larger scales, hence earlier times, is through spectator fields [22,23], whose field displacements are sensitive to a much longer phase of the inflationary epoch and which can be observationally accessible [24].

Since current CMB measurements are compatible with single-field models of inflation (if the potential is of the plateau type) [25–27], such extra fields are not required by the data. However, from a model building perspective, they are ubiquitous in many high-energy embeddings of inflation, e.g., in the context of string theory [28–33]. It is, of course, always possible to fit the data with complex multifield inflationary models, but the amount of fine tuning required in these models may be large, which is why models should be compared in a Bayesian framework that correctly accounts for the waste of parameter space.

The question we ask in this Letter is therefore twofold. Are there multiple-field models of inflation that are as favored by the data as single-field plateau inflation from a Bayesian perspective? What insight can be gained on the inflationary history in these models?

We investigate these questions in one of the simplest extensions to single-field inflation where [34–39] a light (with respect to the Hubble scale) energetically subdominant quadratic spectator scalar field \( \sigma \), called the “curvaton,” sources primordial density perturbations together with the inflaton field \( \phi \). Denoting the effective mass of the curvaton by \( m_\sigma \), the potential is of the form\(^1\)

\[
V(\phi, \sigma) = U(\phi) + \frac{m_\sigma^2}{2} \sigma^2. 
\]

After inflation, the inflaton field decays into radiation and the energy density contained in the curvaton field, \( \rho_\sigma \), may

---

\(^1\)For the sake of simplicity, we neglect self-interactions in the spectator potential; in a more general setting those terms could only be neglected for sufficiently massive spectators.
grow relative to the background energy density, until it also decays into radiation. Assuming that no isocurvature perturbations persist [40–42], the total adiabatic power spectrum is given by the sum of the power spectra of the perturbations originating from each field,

\[ P^\text{total}_\zeta = P^\phi_\zeta + P^\sigma_\zeta, \]  

(2)

where in the case of observational interest, \( \sigma_\zeta \ll M_\text{Pl} \) (since \( \sigma_\zeta \sim M_\text{Pl} \) is disfavored by the data, see footnote 4,

\[ P^\phi_\zeta = \frac{1}{2e_\lambda} \left( \frac{H_\zeta}{2\pi M_\text{Pl}} \right)^2 \]

and

\[ P^\sigma_\zeta = r^2_\text{dec} \left( \frac{H_\zeta}{3\pi\sigma_\zeta} \right)^2. \]

(3)

Here, a star denotes the time when the pivot scale \( k_\ast = 0.05 \text{ Mpc}^{-1} \) crosses the Hubble radius, \( H = \dot{a}/a \) is the Hubble scale where a dot denotes derivative with respect to cosmic time, \( c = -\dot{H}/H^2 \) is the first slow-roll parameter, \( M_\text{Pl} \) is the reduced Planck mass, and \( r_\text{dec} \) is a parameter that quantifies the relative energy density of the curvaton at its decay. In the sudden-decay approximation [43,44],

\[ r_\text{dec} \approx \left( \frac{3\rho_\sigma}{3\rho_\sigma + 4\rho_{\text{radiation}}} \right)_\text{dec}. \]

(4)

This quantity can vary from zero to unity in the case that \( \sigma \) dominates the background energy density at the time it decays.

Observations are often discussed in terms of the spectral index \( n_S \equiv 1 + d \ln P^\text{total}_\zeta/d \ln k \) and the tensor-to-scalar ratio \( r \equiv P_T/P^\text{total}_\zeta \) (where \( P_T \) is the tensor power spectrum) given by [45]

\[ n_S - 1 = \lambda (-2e_\lambda + 2\eta_\sigma) + (1 - \lambda) (-6e_\lambda + 2\eta_\phi), \]

\[ r = 16e_\lambda (1 - \lambda). \]

(5)

Here, \( \eta_\phi = V_{,\phi\phi} / (3H^2) \) and \( \eta_\sigma = V_{,\sigma\sigma} / (3H^2) \), \( V_{,x} \) (\( V_{,xx} \)) denotes the first (second) derivative of \( V \) with respect to \( x \), and \( \lambda \) denotes the fraction of the total perturbations originating from \( \sigma \),

\[ \lambda \equiv \frac{P^\sigma_\zeta}{P^\text{total}_\zeta}. \]

(6)

When the primordial density perturbation is entirely due to the spectator field fluctuations then the original curvaton model [36–38] is realized. Hence in this work, we term situations where \( \lambda > 0.9 \) as the “curvaton scenario”.

At the pivot scale, the latest 2015 BICEP2/Keck Array and Planck [14,46] combined observations give \( P^\text{total}_\zeta \sim 2.2 \times 10^{-9} \), \( n_S = 0.9667 \pm 0.0008 \) (95% C.L.) and \( r < 0.07 \) (95% C.L.). If the inflaton potential is of the large-field type \( U(\phi) \propto \phi^p \), in the curvaton limit \( \lambda \approx 1 \), Eq. (5) implies that \( n_S \approx 1 - p/120 \), and the observed value of the spectral index means that the inflaton field potential must be close to quartic, \( p = 4 \). The “simplest” curvaton scenario with a quadratic inflaton is now disfavored by the data [47–50].

The observational constraints on \( n_S \) and \( r \) imply that when any inflaton potential is included in the analysis, only two classes of models with an additional spectator field are found to be favored [49]: plateau inflation, which cannot fit the data in the curvaton scenario (thereby requiring \( \lambda \ll 1 \)), and quartic inflation, which can only fit the data in the curvaton scenario (\( \lambda \sim 1 \)). An advantage of a quartic potential is that the inflaton field energy decreases like radiation when it oscillates, making the model more predictive by removing the dependence of postinflationary dynamics on the inflaton decay rate into radiation.

Another way to detect the curvaton is through primordial nonlinearity of the density perturbations, of which the key observable is the local non-Gaussianity of the bispectrum, parametrized by \( f_{NL} \). In the sudden-decay approximation [51,52],

\[ f_{NL} \approx \lambda^2 \left( \frac{5}{4r_\text{dec}} - \frac{5}{3} - \frac{5r_\text{dec}}{6} \right), \]

(7)

where the observational non-Gaussianity constraint of \( f_{NL} = 0.8 \pm 5.0 \) (68% C.L.) [53] implies that either we predominantly observe inflaton perturbations, \( \lambda \approx 0 \), or the spectator must have a non-negligible energy density at its decay, \( r_\text{dec} \gtrsim 0.1 \).

The contribution from the curvaton to the primordial power spectrum crucially depends on its field value, \( \sigma_\zeta \), when observable modes exit the Hubble radius. Combining Eqs. (3) and (6), the curvaton dominates the perturbations, \( \lambda > 1/2 \), if \( \sigma_\zeta / M_\text{Pl} < \sqrt{c_\zeta} r_\text{dec} \). Therefore \( \sigma_\zeta \) must be sub-Planckian (if it is super-Planckian, it may drive a second phase of inflation and the above formulas do not apply, but we show in footnote 4 that this case is excluded). The value of \( \sigma_\zeta \) is determined by the details of the inflaton’s potential \( U(\phi) \) over the entire inflating domain, as recently shown in Ref. [22]. This makes the model more predictive since the typical value of \( \sigma_\zeta \) is not a free parameter anymore. This will play an important role in the Bayesian analysis below. In particular, the value of \( \sigma_\zeta \) depends on the total duration of inflation, which will allow us to constrain it.\(^2\)

II. PRIORS

Most previous analyses of curvaton models assumed no knowledge a priori about spectator field values. Instead, we adopt a physical prior for the typical field displacement \((\sigma_\zeta)^{1/2}\) of the curvaton [22], calculated in the framework of stochastic inflation [56], which describes how, during inflation, the vacuum expectation value (vev) of spectators

\(^2\)For a related approach in the context of light vector fields, see [54,55].
fields on super-Hubble scales are sourced by quantum fluctuations. This prior depends on the inflaton potential $U(\phi)$ and the total duration of inflation.

In the presence of a plateau inflationary potential (here we choose Higgs inflation\cite{57}, whose potential matches the Starobinsky model\cite{7}, to be the representative member of this class), if inflation lasts more than $N = H^2/m^2_f$ e-folds\cite{56,58}, the vev of $\sigma$ reaches a Gaussian equilibrium distribution with vanishing mean, and variance

$$\langle \sigma^2 \rangle = \frac{3H^4}{8\pi^2m_\sigma^2}.$$  \hspace{1cm} (8)

In the presence of a quartic large-field inflationary potential ($U(\phi) \propto \phi^4$), we find a zero-mean Gaussian with variance

$$\langle \sigma^2 \rangle = \langle \sigma^2_{\infty} \rangle + \frac{H^2_s}{12\pi^2}N_{\text{tot}},$$  \hspace{1cm} (9)

with a strong dependence upon initial conditions, as was shown to be the case for a large field inflationary background with monomial power $\geq 2$ in Ref.\cite{22}. Above, $N_{\text{tot}}$ is the total number of e-folds elapsed during quartic inflation and $\langle \sigma^2_{\infty} \rangle$ denotes the variance of the curvaton vev distribution at the onset of inflation. The distributions (8) and (9) define the prior on $\sigma$, for plateau and quartic inflation, respectively.

The expansion history of reheating depends on the mass of the curvaton and the decay rates, $\Gamma$, of the inflaton and the curvaton.\footnote{Here, $\Gamma_\phi$ (or $\Gamma_\sigma$) denotes the value of $H$ below which the energy density contained in $\phi$ (or $\sigma$, respectively), or its decay products, redshiftlike radiation.} Through noninformative priors (see Appendix), we impose that the onset of the radiation-dominated period occurs after the end of inflation and before the electro-weak symmetry breaking. We also assume that the inflaton and the curvaton decay at least as fast as they would through their minimal coupling to the gravitational sector, $\Gamma > m^3/M^2_{Pl}$ \cite{59}. As noted earlier, if the inflaton has a quartic potential, its coherent oscillations around the minimum of its potential give rise to a radiation-like era of expansion immediately after inflation \cite{60}. In this case, reheating can be described by two parameters only, the mass and decay rate of the curvaton.

III. RESULTS

The Bayesian analysis is performed on the January 2015 BICEP2/Keck-Array/Planck data combination \cite{61}, using the machine-learned effective inflationary likelihood described in Ref.\cite{62}, which has been marginalized over late-time background cosmology, reionization, and astrophysical foregrounds. The predictions of the models are computed with the curvaton extension of the ASPIC library \cite{63}, making use of the method presented in Refs.\cite{21,49}.

The Bayesian evidence is integrated using MultiNest \cite{64,65}; further technical details on the numerical integration can be found in the Appendix. The Bayesian evidence is displayed in Fig. 1 and the corresponding posterior distributions in Fig. 2.

A. Single-field versus spectator model

One can check in Fig. 1 that for single-field models, plateau potentials are favored while a quartic potential is strongly disfavored (and even ruled out at the level of its maximum likelihood). When a light spectator field is included, the evidence of plateau potentials remains stable, and the two-field model cannot be distinguished from its single-field counterpart in terms of its Bayesian evidence \cite{66}. This is because, in spite of the significant enlargement in prior parameter space caused by the introduction of the spectator field, most of the prior mass in the distribution (8) reproduces single-field phenomenology, which gives a very good fit to the data irrespective of the value of the reheating parameters. This result is consistent with Refs.\cite{21,49}.

For the quartic potential, the evidence obtained once a spectator field is included depends on the total duration of inflation, $N_{\text{tot}}$, and the variance of the curvaton vev distribution at the onset of inflation, $\langle \sigma^2_{\infty} \rangle$, through the prior distribution (9) for the curvaton vev. We give the Bayesian evidence for a few values of $N_{\text{tot}}$ in Fig. 1, taking $\langle \sigma^2_{\infty} \rangle = 0$, and $N_{\text{tot}} \sim 6 \times 10^4$ as an upper bound, since for larger values the inflaton would initially be in the “self-reproducing” regime \cite{67,68} where stochastic corrections to its dynamics become important and the calculation of Ref.\cite{22} does not apply; however, we are protected from this limit by the fact that it is disfavored observationally, since it would locate
most of the prior mass in spectator vevs so large that they drive a second phase of quadratic inflation.\footnote{If the light spectator field is displaced by $\sigma_{\xi}^2 \gtrsim 2M_{\text{Pl}}^2$ during inflation, then it may drive a second period of inflation, which lasts for $N_2 \approx \sigma_{\xi}^2/(4M_{\text{Pl}}^2)$ e-folds. The amplitude of the curvaton perturbations generated during the first period of inflation is [69]}  

In all cases, quartic models with a spectator field are favored with respect to their single-field counterpart, but are still moderately or strongly disfavored with respect to the plateau potential.  

In terms of the observables shown in Fig. 2, plateau inflation (the Higgs inflation or Starobinsky model in the present case) with a spectator field presents similar phenomenology to its single-field counterpart, namely a small tensor-to-scalar ratio and a slow-roll suppressed value for $f_{\text{NL}}$ that is currently (and in the foreseeable future) undetectable. For quartic inflation, independently of the duration of inflation, the tensor-to-scalar ratio and the spectral index are correlated, with bluer spectra corresponding to reduced gravitational waves, and non-Gaussianity has the typical amplitude $f_{\text{NL}} \approx -5/4$, which, from Eq. (7), corresponds to a preference for values $\lambda \approx r_{\text{dec}} \approx 1$, i.e., to situations where the curvaton dominates the energy budget of the Universe when it decays and provides the dominant contribution to primordial density perturbations.  

Post-2020 CMB experiments [70–72] will shrink the 1-sigma constraints on the inflationary observables to $\Delta n_S \sim 2 \times 10^{-3}$ and $\Delta r \sim 10^{-4}$, while cross-correlation with future LSS experiments should drive the constraint on local non-Gaussianity down to $\Delta f_{\text{NL}} \sim 0.4$ [73]. This would be enough to distinguish between plateau inflation (with or without a spectator field) and quartic inflation with a curvaton, or even to rule out both models.

B. Measuring the maximum duration of inflation  

For quartic potentials with a spectator field, the data shows strong preference for curvaton phenomenology, which corresponds to sub-Planckian spectator field values of a few $10^{-2}M_{\text{Pl}}$. This yields an “optimal” value for the variance of the prior distribution (9), such that it maximizes the parameter volume that falls within this range of values.  

A smaller variance limits the spectator field vev so that single-field quartic inflation is recovered, which is ruled out observationally. A larger variance locates most of the prior mass in spectator vevs so large that they drive a second phase of quadratic inflation, which is also ruled out (see footnote 4).

Let us assume $\langle \sigma_{\xi}^2 \rangle = 0$ in Eq. (9). In that case, using Bayes theorem, the posterior on the total duration of inflation can be computed according to

$$\mathcal{P}(N_{\text{tot}}|D) \propto \mathcal{P}(D|N_{\text{tot}})\pi(N_{\text{tot}}),$$

where $\mathcal{P}(D|N_{\text{tot}}) = Z(N_{\text{tot}})$ is the evidence of the quartic plus spectator field model with prior (9) on $\sigma_\xi$ corresponding to
because in such cases, Eq. (9) yields inflation starts close to the "self-reproducing" regime, $N_{\text{tot}} \sim 6 \times 10^4$. The dotted line and the grey band are respectively the mean and 1-sigma confidence-level limit of a logarithmic Gaussian process interpolation with maximum-$\alpha$-posteriori noise level, scale and correlation length [74]. The black dots and bars are the evidence and their errors computed with MultiNest.

to $N_{\text{tot}}$, and $\pi(N_{\text{tot}})$ is the prior we set on the duration of inflation.

We reconstruct this posterior in Fig. 3, where one can see that inflation is constrained to last less than a few tens of thousands of $e$-folds. In particular, cases where inflation starts close to the "self-reproducing" regime ($N_{\text{tot}} \sim 6 \times 10^4$), are strongly disfavored [75]. This is because in such cases, Eq. (9) yields $(\sigma_i^2)^{1/2} > M_{\text{pl}}$ (which is true in any large-field inflationary potential [22]) and the spectator field drives a second phase of inflation.

If the initial variance $\langle \sigma_i^2 \rangle$ does not vanish then the constraint that we have obtained becomes an upper bound on the duration of inflation, and the conclusion that inflation should not start in the self-reproducing regime becomes even stronger.

IV. CONCLUSION

If inflation is realized in the presence of light spectator fields, which appear in many high-energy embeddings of inflation, then those fields may source part or all of the primordial density perturbations. Recent CMB measurements have now reached a level of accuracy such that there is no inflationary potential for which the single-field limit, where all perturbations come from the inflaton field, and the curvaton limit, where all perturbations come from a spectator field, are both allowed by the data. This is why, for the first time, we are in a position where a Bayesian model comparison of inflationary models with spectator fields yields nontrivial results.

For instance, we have found that if the potential is of the plateau type, the single-field limit is the preferred one (the predictions of the model are robust under the introduction of a spectator field), while quartic potentials are favored only in the curvaton limit. Both combinations are equally favored by current data, but we have shown that future CMB and LSS measurements will allow us to distinguish between them.

The contribution from spectator fields to cosmological perturbations strongly depends on their field values at the end of inflation [22]. The accumulation of long-wavelength quantum fluctuations during the entire inflationary period gives rise to a distribution for the local field displacement that depends on the total duration of inflation $N_{\text{tot}}$, plus a possible contribution at the onset of inflation $\langle \sigma_i^2 \rangle$. As a consequence, a combination of both parameters can be constrained by the data.

In the curvaton limit, the inflationary potential is constrained to be close to the quartic type. In that case, spectator field values that are too small would fail to source cosmological perturbations, and too large values would drive a second phase of inflation, which is observationally disfavored.

Assuming $\langle \sigma_i^2 \rangle = 0$, we compute the posterior distribution on $N_{\text{tot}}$ (see Fig. 3) and find that inflation could not last more than a few tens of thousands of $e$-folds. In particular, it is very unlikely that one starts quartic inflation in the so-called "self-reproducing" regime. Letting $\langle \sigma_i^2 \rangle > 0$ makes that upper bound even stronger.

For the first time, we have thus quantified how much cosmological data can constrain the pre-inflationary history, much beyond the $N \gtrsim 60$ epoch probed by potential large scale CMB anomalies. One should note that the mechanism we presented is not only sensitive to the duration of inflation but also on the shape of the inflationary potential over its entire inflating domain, and on the spectator field displacement prior to inflation. This opens up a new observational window that extends the conventional scales by orders of magnitude and allows us to explore the physics of the very early Universe beyond our currently observable horizon.

APPENDIX: DETAILS ON THE PRIORS AND THE COMPUTATION OF THE EVIDENCE

The non-informative prior described in the paper on the reheating parameters, the mass of the curvaton and the decay rates $\Gamma$ of the inflaton and the curvaton, is

$$\Gamma_\sigma \sim \log \mathcal{U} \left[ \max \left( \frac{H_{\text{EW}} m_\sigma^3}{M_{\text{Pl}}^2} , \min \left( H_{\text{end}} , m_\sigma \right) \right), \right] ,$$

$$\Gamma_\phi \sim \log \mathcal{U} \left[ \max \left( \frac{H_{\text{EW}} H_{\text{end}}^3}{M_{\text{Pl}}^2} , H_{\text{end}} \right) , \right] ,$$

$$m_\sigma \sim \log \mathcal{U} \left[ H_{\text{EW}} , H_{\text{end}} \right] ,$$

where $H_{\text{end}}$ is the Hubble scale at the end of inflation, $H_{\text{EW}} = (150 \text{ GeV})^2/M_{\text{Pl}}$ is the Hubble scale at electroweak symmetry breaking, and $x \sim \log \mathcal{U} [a,b]$ means that $\log x$ is uniformly distributed between $\log a$ and $\log b$.

In the quartic inflaton case, the radiationlike reheating of the inflaton, described as $\Gamma_\phi = H_{\text{end}}$, is imposed via a half log-normal $\log_{10}(\Gamma_\phi) \sim N_{1/2} \left[ \log_{10}(H_{\text{end}}) , (1/2)^2 \right]$. This needs to be done for numerical purposes, since $H_{\text{end}}$ is a derived quantity that depends on both parameter combinations and can only be computed a posteriori.

In the models presented in this paper, the total power of the primordial density perturbations constitutes an additional free parameter, which we have omitted because it affects both models equally. For numerical purposes, we use a log-uniform prior which comfortably contains the posterior observed by Planck for this parameter. Thus, the total parameter space sampled is $(\Gamma_\phi , \Gamma_\sigma , m_\sigma , \sigma_{\text{end}} , A_\phi)$, and our posteriors and evidence are conditioned to the model producing close to the right amount of power.

We ensure the correct normalization of the evidence by dividing the marginal likelihood by the total prior mass in the same parameter domain, obtained with a quick MultiNest integration of a mock unit likelihood. All results are obtained with $1000$ live points and a very low sampling efficiency of $0.01$ (i.e., inverse of ellipsoid enlargement factor). A significant enlargement of the ellipsoids is needed to properly account for the hard edges of the prior and the fact that in the quartic case the mode of the spectator field value is located at the edge of the prior (otherwise, if a mode at the edge of the prior is partially or totally missed by the initial sample of live points, the final evidence will be undervalued). This low efficiency produces a lot of rejected points that spoil the computation of the weights used by the Importance Nested Sampling estimator [76], what makes it numerically unstable, most often severely undervalued. Thus, we use the standard nested sampled estimator in this paper.
