Abstract: For several computational procedures such as finding radicals and
Noether normalizations, it is important to choose as sparse as possible a system
of parameters in a polynomial ideal or modulo a polynomial ideal. We describe
new strategies for these tasks, thus providing solutions to problems (1) and (2)
posed in [Eisenbud-Huneke-Vasconcelos 1992].

To accomplish the first task we introduce a notion of “setwise complete in-
tersection”. We prove that a set of monomials generating an ideal of codimension
$\text{c}$ in a polynomial ring can be partitioned into $\text{c}$ disjoint sets forming a setwise
complete intersection, although the corresponding result is false for arbitrary sets
of polynomials. We reduce the general case to the monomial case by a deforma-
tion argument. For homogeneous ideals the output is homogeneous. Our analysis
of the second task is based on a concept of Noether complexity for homogeneous
ideals and its characterization in terms of Chow forms.

Introduction

Let $k$ be a field and let $S := k[x_1, \ldots, x_m]$ be the polynomial ring. Let $J$ be an ideal
of $S$, possibly 0, and let $R = S/J$. Given a finite set $\mathcal{F} \subset R$, generating a proper
ideal $I$, it is a prerequisite for many algebraic computations to find a maximal system of
parameters in the ideal $I$. By this we mean a system of $\text{codim}(I)$ elements of $I$ which
generate an ideal of the same codimension; see for example [Eisenbud-Huneke-Vasconcelos
1992, Eisenbud 1993, Krick-Logar 1991, and Vasconcelos 1993a,b]. The feasibility of the
subsequent computation often hinges on the fact that the system of parameters is “nice”;
typically, that it consists of polynomials which are reasonably sparse, and of low degree.

In this paper we address the question of how to compute a system of parameters which
is as sparse as possible. Given a set of polynomials $\mathcal{F}$ that generate an ideal of codimension
$c$, we study the ways of dividing $\mathcal{F}$ into subsets $\mathcal{F}_1, \mathcal{F}_2, \ldots, \mathcal{F}_c \subseteq \mathcal{F}$ such that if $f_i$ is a
sufficiently general linear combination of elements from $\mathcal{F}_i$ then $f_1, \ldots, f_c$ form a system of parameters modulo $J$.

In the first section we treat the case $J = 0$. This arises when computing the radical of an ideal. Our main result in this case is Theorem 1.3, which says that if the elements of $\mathcal{F}$ are monomials, and somewhat more generally, then the $\mathcal{F}_i$ may be chosen to be disjoint subsets of $\mathcal{F}$. We give examples to show that this result fails for arbitrary polynomials, but we can reduce the general case to this one by a deformation argument, using partial Gröbner bases. Although it is unpleasant to have to compute a Gröbner basis for this purpose, and the worst-case complexity of the computation is certainly very bad, the payoff is high: if the input polynomials are homogeneous of varying degrees, the output can be made homogeneous without any loss of sparseness from the inhomogeneous case.

In the second section we consider the case of arbitrary $J$, and we present a simple “greedy” algorithm (2.1). We then concentrate on the important case when $J$ is homogeneous and unmixed, and $I$ is the ideal $(x_1, \ldots, x_m)$. This is the problem of Noether normalization. In this case we compare some possible meanings of the term “sparse”, with the conclusion that the “correct” measure of sparseness will vary with the application at hand. Choosing one of these, we define the Noether complexity, which is the sparseness of the sparsest possible Noether normalization. It is characterized in terms of the Chow form of $J$ (Theorem 2.7) and can thus be computed in single-exponential time in $m$ (cf. [Caniglia 1990]). Another simple approach to computing a Noether normalization of $J$ is to lift one from any initial ideal of $J$; this lifting method is explained following Proposition 2.8. We demonstrate by explicit examples that, in general, neither this lifting method nor the greedy algorithm attains the Noether complexity.

To simplify the discussion, we assume throughout that $k$ is an infinite field, though in practice any sufficiently large field will do. In order to use our algorithms it is necessary to compute the codimensions of various ideals. Good methods for doing this are discussed in Bayer-Stillman [1992] and Bigatti-Caboara-Robbiano [1993].

Both authors were partially supported by the NSF during the preparation of this paper. The second author was also supported by an A.P. Sloan Fellowship.
1. Systems of parameters in a polynomial ring

We retain the notation of the introduction. In this section we treat the case $J = 0$, and assume that $\mathcal{F}$ is a subset of a proper ideal $I$ of the polynomial ring $S := k[x_1, \ldots, x_m]$.

Some obvious approaches and their drawbacks

Let $c$ be the codimension of $I$. A set of $c$ linear combinations of the polynomials in $\mathcal{F}$ with sufficiently general coefficients in $k$ is a system of parameters, but unfortunately does not have the desired sparseness. Further, if the polynomials in $\mathcal{F}$ are homogeneous but of different degrees and a homogeneous system of parameters is required, then in this approach one must first replace $\mathcal{F}$ by a set of polynomials all of the same degree, for example by multiplying each one by a power of a generic linear form, or by replacing each by the ideal it generates in degree equal to the maximal degree in $\mathcal{F}$. This process dramatically destroys sparseness, and raises the degrees of the elements of $\mathcal{F}$ in a way that seems unnecessary.

It is thus natural to ask for the smallest subsets $\mathcal{F}_1, \mathcal{F}_2, \ldots, \mathcal{F}_c \subseteq \mathcal{F}$ such that the linear combinations

\[
    f_1 = \sum_{f \in \mathcal{F}_1} r_{1,f} \cdot f, \quad f_2 = \sum_{f \in \mathcal{F}_2} r_{2,f} \cdot f, \ldots, \quad f_c = \sum_{f \in \mathcal{F}_c} r_{c,f} \cdot f \quad (\ast)
\]

generate an ideal of codimension $c$ (that is, form a system of parameters) for some choice of coefficients $r_{i,f}$. Supposing that no proper subset of $\mathcal{F}$ generates an ideal of codimension $c$, an optimal result of this type would be to take $\mathcal{F}_1, \mathcal{F}_2, \ldots, \mathcal{F}_c$ to be a partition of $\mathcal{F}$, that is, disjoint subsets whose union is $\mathcal{F}$.

A first hope might be that one could define the sets $\mathcal{F}_j$ inductively by the condition that

\[
    \mathcal{F}_1 \cup \mathcal{F}_2 \cup \ldots \cup \mathcal{F}_j
\]

is the smallest initial subset generating an ideal of codimension $j$. But this is wrong even for monomial ideals as the following example from [Eisenbud 1993] shows:

Cautionary Example 1.1. Let $m = 4$ and $\mathcal{F} := \{x_1x_2, x_2x_3, x_4, x_1x_3\}$. We have $c = 3$ and the partition suggested above is

\[
    \{x_1x_2\}, \{x_2x_3, x_4\}, \{x_1x_3\}.
\]

However, no sequence of the form

\[
    x_1x_2, \lambda x_2x_3 + \mu x_4, x_1x_3
\]

is a system of parameters, since it is contained in the height 2 ideal $(x_1, \lambda x_2x_3 + \mu x_4)$. On the other hand, the partition

\[
    \{x_1x_2\}, \{x_2x_3, x_1x_3\}, \{x_4\}
\]

does have the desired property. ■
Unfortunately, partitions with the desired property need not exist. The following example was worked out in conversation with Joe Harris.

**Cautionary Example 1.2.** Let \( \{ C_{ij} \}_{1 \leq i \leq j \leq 5} \) be any 10 distinct irreducible space curves in \( \mathbb{P}^3 \), and take \( d \) an integer large enough so that for each \( i \) the ideal of the union of the 6 \( C_{pq} \) whose indices \( p, q \) do not include \( i \) is generated by forms of degree \( d \). For \( i = 1, \ldots, 5 \) let \( g_i \) be a general form of degree \( d \) vanishing on these 6 curves \( C_{pq} \). Let \( \mathcal{F} = \{ g_1, \ldots, g_5 \} \).

It is easy to see that \( \mathcal{F} \) has no zeros in \( \mathbb{P}^3 \) and hence generates an ideal of codimension 4.

We claim that there is no partition of \( \mathcal{F} \) into four disjoint subsets \( \mathcal{F}_i \) and choice of coefficients \( r_{i,f} \) such that \((*)\) generates an ideal of codimension 4. If such a partition existed, then 3 of the sets \( \mathcal{F}_i \) would have to be singletons. Hence some 3 forms \( g_i, g_j, g_k \) would have to be a system of parameters, and vanish only at finitely many points in \( \mathbb{P}^3 \).

Since \( g_i, g_j, g_k \) vanish on the curve \( C_{uv} \), where \( \{ i, j, k, u, v \} = \{ 1, \ldots, 5 \} \), this is impossible.

There is no example of this type with \( d = 2 \), but here is one with \( d = 3 \): Let \( p_1, \ldots, p_5 \) be general points in \( \mathbb{P}^3 \), let \( C_{ij} \) be the line passing through \( p_i \) and \( p_j \), and let \( l_{ijk} \) be the equation of the plane containing the three points \( p_i, p_j, p_k \). The 6 lines not involving a particular index \( i \) form a tetrahedron. The ideal of their union is generated by the set \( F_i \) of 4 cubic forms made by taking products, 3 at a time, of the \( l_{stu} \) with \( i \not\in \{ s, t, u \} \), so we may take \( d = 3 \) in the argument above. 

Theorem 1.3 below will show that good partitions do exist for monomial ideals, and this is the basis of our method. The reason that they exist is essentially that a monomial ideal of codimension \( c \) is always contained in an ideal generated by \( c \) elements — in fact, by \( c \) of the variables.

**A method for finding a sparse system of parameters**

The following theorem is our first main result. We fix any term order “\( \prec \)” on the polynomial ring \( S \) and we write \( \text{in}_{\prec} (\mathcal{F}) \) for the set of initial terms of the polynomials in \( \mathcal{F} \).

**Theorem 1.3.** Suppose that \( \text{in}_{\prec} (\mathcal{F}) \) generates an ideal of codimension \( c \). There exist partitions \( \mathcal{F} = \mathcal{F}_1 \cup \ldots \cup \mathcal{F}_c \) such that for each \( i \) the monomials \( \text{in}_{\prec} (\mathcal{F}_i) \) have a variable in common. If \( \mathcal{F} \) is any such partition, then for almost all \( r_{i,f} \in k \), the polynomials \((*)\) generate an ideal of codimension \( c \). Further, each \( f \in \mathcal{F} \) may be multiplied by any factor of \( \text{in}_{\prec} (f) \) without spoiling this property.

It is known that the hypothesis of Theorem 1.3 is satisfied if \( \mathcal{F} \) is a Gröbner basis of an ideal of codimension \( c \). (See e.g. [Kalkbrener-Sturmfels 1993]). This suggests the following algorithm for finding a sparse system of parameters.

**Algorithm 1.3’.**

**Input:** A set of generators \( \mathcal{F} \) for an ideal \( I \) of codimension \( c \)
Enlarge $\mathcal{F}$ step by step toward a Gröbner basis, using the Buchberger algorithm, until $\text{in}_{\prec}(\mathcal{F})$ generates an ideal of codimension $c$. Next replace this partial Gröbner basis by a minimal subset which has the same property. Partition this new $\mathcal{F}$ into subsets $\mathcal{F}_i$ as in Theorem 1.3, for example as follows: Choose a prime $(x_{i_1}, \ldots, x_{i_c})$ containing $\text{in}_{\prec}(\mathcal{F})$.

Such primes exist because every associated prime of a monomial ideal is generated by a subset of the variables. For $p = 1, 2, \ldots, c$ define $\mathcal{F}_p$ inductively to be the set of all elements of $\mathcal{F} - \bigcup_{j \leq p} \mathcal{F}_j$ whose initial terms are divisible by $x_{i_p}$.

If the polynomials in $\mathcal{F}$ are homogeneous, and a homogeneous system of parameters is desired, let $d_i$ be the maximal degree in $\mathcal{F}_i$, and multiply each polynomial in $\mathcal{F}_i$ by a power of one of the variables in its own initial term to bring it up to degree $d_i$.

Choose random elements $r_{i,f}$ in $k$, and verify that the polynomials $f_i$ in $(\ast)$ generate an ideal of codimension $c$. If they do not, try a new random choice.

**Output**: The sequence $f_1, \ldots, f_c$.  

Before starting Algorithm 1.3′, it may be worthwhile to change to the order for which the initial forms of $\mathcal{F}$ generate an ideal of largest possible codimension. This can be done using the polyhedral methods in [Gritzmann-Sturmfels 1993].

One subtask to be solved in Algorithm 1.3′ is to find the minimal prime $(x_{i_1}, \ldots, x_{i_c})$. This is often an easy task, but we remark that in general it amounts to solving a combinatorial problem which is NP-complete. To see this, consider the case where $\text{in}_{\prec}(\mathcal{F})$ consists of square-free quadratic monomials $x_i x_j$, representing the edges of a graph $G$ with vertex set $\{x_1, \ldots, x_m\}$. A subset $S$ of the vertices of $G$ is called *stable* if no two elements in $S$ are connected by an edge in $G$. Our subtask amounts to finding a maximal stable set of $G$, a problem which is known to be NP-complete.

Our proof of Theorem 1.3 is based on the following criterion for a sequence of sets of polynomials to be what one might describe as a “setwise system of parameters”:

**Proposition 1.4.** Let $\mathcal{F}_1, \ldots, \mathcal{F}_c \subset S$ be sets of polynomials. If for every $U \subseteq \{1, \ldots, c\}$ the set of polynomials $\bigcup_{j \in U} \mathcal{F}_j$ generates an ideal of codimension $\geq \text{card } U$, then for almost every choice of $r_{i,f}$ in $k$ the polynomials $f_1, \ldots, f_c$ in $(\ast)$ generate an ideal of codimension $c$ in $S$.

**Remarks.**

(i) The term “for almost every choice” in Proposition 1.4 (and the term “random” in Algorithm 1.1) means that $r_{i,f}$ can be chosen in some Zariski-open subset of the coefficient space.

(ii) Example 1.1 shows that we cannot weaken the hypothesis by restricting $U$ to be an initial subset of $\{1, \ldots, c\}$.

(iii) The converse of Proposition 1.4 holds after localizing at any prime containing all the
F_i's. (Reason: In a local domain with saturated chain condition, codim (f_1, \ldots, f_c) = c implies codim (f_1, \ldots, f_d) = d for all d < c.) It follows that it holds, even without localizing, if each F_i consists of homogeneous polynomials of positive degree. (Reason: The local codimension of the ideal generated by \bigcup_{j \in U} F_j is minimized in the localization at the origin.)

The following example shows that the converse is false in general. We are grateful to Alicia Dickenstein for pointing it out.

Cautionary Example 1.5. Let m = 3, F_1 = \{ f_1 = (x_1+1)x_2 \}, F_2 = \{ f_2 = (x_1+1)x_3 \}, and F_3 = \{ f_3 = x_1 \}. Then f_1, f_2, f_3 generate an ideal of codimension 3 but f_1, f_2 generate an ideal of codimension 1.

Proofs

Proof of Proposition 1.4. We first show that the conclusion holds in the “generic situation”. Let k' be the polynomial ring with variables r_{i,f} for f \in F_i and i = 1, \ldots, c. We will show that the polynomials f_1, \ldots, f_c in (*) generate an ideal of codimension c in S \otimes_k k'. Equivalently, let A be the affine space with the r_{i,f} as coordinates, and let B be the affine space with coordinates x_1, \ldots, x_m. Let X be the subvariety of A \times B defined by f_1, \ldots, f_c. We will show that the codimension of X is c.

Let \pi_2 : X \to B be the projection to the second factor of the product. The fiber of \pi_2 over a point p \in B is a linear space. Since the f_i involve disjoint sets of variables r_{i,f}, its codimension equals c minus the number of indices i such that the polynomials in F_i all vanish at p. For each subset U \subseteq \{1, \ldots, c\} let Y_U denote the set of p \in B such that the polynomials in \bigcup_{j \in U} F_j all vanish at p but some polynomial in each F_j for j \notin U does not vanish at p. The constructible sets Y_U define a stratification of B such that over each stratum the fibers of \pi_2 have constant codimension c - card U. Therefore the codimension of X in A \times B equals min\{ c - card U + codim Y_U : U \subseteq \{1, \ldots, c\} \}. The hypothesis in (c) states that if Y_U is nonempty, then the codimension of Y_U is \geq card U. We conclude that the codimension of X is \geq c.

To conclude the proof, consider the projection \pi_1 : X \to A to the first factor of the product. We must show that the codimension in B of almost every fiber of \pi_1 is \geq c. For any dominant map of irreducible varieties, almost every fiber has dimension equal to the dimension of the source minus the dimension of the target. Thus in our situation almost every fiber has codimension in B equal to the codimension in A \times B of the union of those components of X that dominate A. This second codimension is \geq the codimension of X in A \times B, which we have shown to be \geq c.

Proof of Theorem 1.3. The codimension of the ideal generated by the initial terms of a set of polynomials is \leq that of the ideal of the polynomials themselves. Thus if the sets
\[ \text{in}_< (F_i) \] satisfy the hypothesis of Proposition 1.4, then so do the sets \( F_i \). Consequently it suffices to treat the case where \( F \) consists of monomials. We must find a partition satisfying the first condition of Theorem 1.3, and show that any such partition satisfies the hypothesis of Proposition 1.4.

Since every associated prime of a monomial ideal is generated by a subset of the variables, we may assume (after renumbering variables if necessary) that \( F \) is contained in the ideal \((x_1, \ldots, x_c)\). Since a monomial is contained in this ideal if and only if it is divisible by one of the variables \((x_1, \ldots, x_c)\), we may partition \( F \) into subsets \( F_i \) consisting only of monomials divisible by \( x_i \). The following lemma concludes the proof:

**Lemma 1.6.** Let \( F_i \subseteq (x_i) \subseteq S, \ i = 1, \ldots, c \) be sets of monomials. If \( F = \bigcup_{j=1}^c F_j \) generates an ideal of codimension \( c \), then the \( F_j \) satisfy the hypothesis of Proposition 1.4.

**Proof.** For any subset \( U \) as in condition (c), let \( I_U \) denote the ideal generated by \( \bigcup_{j \in U} F_j \). The ideal \( I \) generated by \( F \) is contained in \( I_U + (\{x_i\}_{i \notin U}) \). Since \( I \) has codimension \( c \), the Principal Ideal Theorem implies that \( I_U \) has codimension \( \geq \text{card } U \) as required. □

**Cautionary Example 1.7.** Let \( F_i \) and \( \text{in}_< (F_i) \) be as in Theorem 1.3, and choose coefficients \( r_{i,f} \) such that the linear combinations of initial terms

\[
\sum_{f \in F_1} r_{1,f} \cdot \text{in}_< (f), \ldots, \sum_{f \in F_c} r_{c,f} \cdot \text{in}_< (f)
\]

form a system of parameters. It is tempting to hope that the \( f_i \) in (\( * \)), made with the same coefficients \( r_{i,f} \), would also form a system of parameters. This is not true: If \( F_1 = \{x_1^2 - x_2^2\} \) and \( F_2 = \{x_1 x_2, x_2^2\} \) then \( x_1^2, x_1 x_2 + x_2^2 \) is a regular sequence but \( x_1^2 - x_2^2, x_1 x_2 + x_2^2 \) is not. □

We close Section 1 with two propositions showing that our examples 1.1 and 1.2 are minimal in a certain sense. The proofs are straightforward and will be omitted.

**Proposition 1.8.** Suppose that \( F \subset S \) generates an ideal of codimension \( c \) and that \( F \) cannot be partitioned into subsets \( F_1, \ldots, F_c \) such that for some choice of coefficients \( r_{i,f} \) the polynomials (\( * \)) form a system of parameters.

(a) The set \( F \) can be replaced by a set of \( c + 1 \) linear combinations of the elements of \( F \) having the same property, possibly after reducing \( c \).

(b) Factoring out \( m - c \) general linear forms, the number of variables of \( S \) may be taken to be \( c \).

Thus the critical case concerns sets of \( c + 1 \) polynomials generating an ideal of codimension \( c \) in \( c \) variables. It is most interesting to look at the case of homogeneous polynomials. Example 1.2 is of this kind, with \( c = 4 \), but there are no such examples with \( c \leq 3 \):
Proposition 1.9. If $\mathcal{F} = \{f_1, f_2, f_3, f_4\}$ is a set of homogeneous polynomials in 3 variables, generating an ideal of codimension 3 in $S = k[x_1, x_2, x_3]$, then there is a partition of $\mathcal{F}$ into 3 subsets $\mathcal{F}_i$ such that the polynomials in $(\ast)$ form a system of parameters.

2. Systems of parameters modulo an ideal

We now turn to the general case of our problem, keeping the notation $S := k[x_1, \ldots, x_m]$ as in the introduction. Let $J \subset S$ be an ideal, let $R = S/J$ and let $\mathcal{F} \subset S$ be a finite subset. Let $I$ be the ideal generated by $\mathcal{F}$, and suppose that the codimension of $I$ modulo $J$ is $c$ in the sense that $c = \text{codim}(I + J) - \text{codim}(J)$.

We say that $f_1, \ldots, f_c \in I$ is a maximal system of parameters for $I$ modulo $J$ if $\text{codim}(P + (f_1, \ldots, f_c)) \geq \text{codim}(I + J)$ for every minimal prime $P$ of $J$. (This notion is most natural if the ideal $J$ is unmixed.) We wish to choose as sparse as possible a maximal system of parameters for $I$ modulo $J$.

The simplest and most common problem calling for systems of parameters is that of finding a Noether normalization for a homogeneous ideal. If $c$ is the Krull dimension of $R$, this is the problem of finding elements $f_1, \ldots, f_c$ in $R$ such that $R$ is a finitely generated module over the subring $k[f_1, \ldots, f_c] \subseteq R$. (The elements $f_1, \ldots, f_c$ are then necessarily algebraically independent, so that the subring is isomorphic to a polynomial ring. See [Logar 1988] and [Dickenstein, Fitchas, Giusti, and Sessa 1991] for a discussion from a computer algebra point of view.) We will focus primarily on this case, but first we present a method for handling the general problem. The approach differs from that of Section 1 in that it chooses one $f_i$ at a time, essentially employing overlapping sets $\mathcal{F}_i$.

Greedy Algorithm 2.1.

Input : A set of generators $\mathcal{F}$ for an ideal $I$ of codimension $c$ modulo $J$.

Let $\mathcal{F}_1$ be a minimal subset of $\mathcal{F}$ such that $\mathcal{F}_1$ is not contained in any minimal prime of $J$ of maximal dimension. Let $f_1$ be a sufficiently general combination of the elements of $\mathcal{F}_1$ so that the codimension of $J + (f_1)$ is larger than that of $J$. Let $\mathcal{F}'$ be the result of dropping any one of the elements of $\mathcal{F}_1$ from $\mathcal{F}$. Replace $J$ by $J + (f_1)$, replace $\mathcal{F}$ by $\mathcal{F}'$, and iterate the process.

Output : The sequence $f_1, \ldots, f_c$.

In case the data $\mathcal{F}, I, J$ are homogeneous and the output desired is homogeneous, but not all the polynomials of $\mathcal{F}$ are of the same degree, the “sufficiently general linear combination” would have to have coefficients that are polynomials of varying degrees. The following variation may be an improvement:

Given a minimal subset $\mathcal{F}_1 \subseteq \mathcal{F}$ not contained in any minimal prime of $J$ of maximal dimension, replace it with a set of elements whose initial forms are not contained in any minimal prime of $\text{in}(J)$ of maximal dimension. (This may be done by moving step by step
toward a Gröbner basis of $J + (\mathcal{F}_1)$, using the Buchberger algorithm, until the codimension of the initial ideal is larger than that of the initial ideal of $J$.) Then, if homogeneous output is desired, each element of $\mathcal{F}_1$ not of maximal degree may be multiplied by variables dividing its initial term to bring all the elements of $\mathcal{F}_1$ to the same degree before forming the linear combination as above.

We now turn to the special case of Noether normalization. The following well-known version of Hilbert’s Nullstellensatz makes clear the nature of our task:

**Proposition 2.2.** Let $J$ be a homogeneous ideal of $S$, and set $R = S/J$. Let $X \subset \mathbb{P}^{m-1}$ be the corresponding projective algebraic set. Suppose that the ground field $k$ is algebraically closed. If $f_1, \ldots, f_c \in R$ are homogeneous polynomials, then $R$ is a finitely generated module over the subring $k[f_1, \ldots, f_c] \subseteq R$ if and only if the system of equations $f_1(x) = \ldots = f_c(x) = 0$ has no solution in $X$.

*Proof Sketch:* By the Nullstellensatz the condition that there are no solutions is equivalent to the condition that $R/(f_1, \ldots, f_c)$ is a finite dimensional vector space. Because $R$ is graded and zero in negative degree, a basis for this space lifts to a finite set of generators for $R$ over the subring $k[f_1, \ldots, f_c]$. ■

In the Noether normalization problem one usually wants the $f_i$ to be linear forms. We will henceforth consider only this case, and suppose that $\mathcal{F} = \{x_1, \ldots, x_m\}$, so that $I = (\mathcal{F})$ is the irrelevant ideal. In this situation Algorithm 2.1 has the effect of reducing at each step the number of variables to be considered, and this increases its efficiency. Here is a monomial example, which also suggests a possibility for improving the algorithm:

**Example 2.3.** Let $m = 6$, $c = 2$, $\mathcal{F} = \{x_1, x_2, x_3, x_4, x_5, x_6\}$, and

$$J = (x_1 x_2, x_1 x_3, x_2 x_3, x_2 x_4, x_2 x_5, x_3 x_4, x_3 x_5, x_4 x_5, x_4 x_6, x_5 x_6) = (x_1, x_2, x_4, x_5) \cap (x_1, x_3, x_4, x_5) \cap (x_2, x_3, x_4, x_5) \cap (x_2, x_3, x_4, x_6) \cap (x_2, x_3, x_5, x_6).$$

In the first step the unique optimal choice is $\mathcal{F}_1 = \{x_1, x_6\}$. We set $f_1 = x_1 - x_6$ and remove $x_1$ from $\mathcal{F}$. Repeating the procedure with

$$J + (f_1) = (x_1 - x_6, x_2 x_3, x_2 x_4, x_2 x_5, x_2 x_6, x_3 x_4, x_3 x_5, x_3 x_6, x_4 x_5, x_4 x_6, x_5 x_6),$$

we must use all remaining variables: $\mathcal{F}_2 = \{x_2, x_3, x_4, x_5, x_6\}$. For the second parameter we can choose, for instance, $f_2 = x_2 + x_3 + x_4 + x_5 + x_6$. ■

In general Algorithm 2.1 is “too greedy”: it does not perform optimally with respect to sparseness. For example,

$$\hat{f}_1 = x_1 + x_2 + x_3, \quad \hat{f}_2 = x_4 + x_5 + x_6.$$
is also a Noether normalization for the ideal $J$ in Example 2.3. It has a total of only six non-zero terms, while the output $f_1, f_2$ of Algorithm 2.1 has seven non-zero terms.

This shows that the subtlety of sparse Noether normalization is not completely captured by Algorithm 2.1. The remainder of this paper is devoted to a more thorough combinatorial analysis, leading to an optimal result.

**Sparsity of Linear Subspaces**

We begin with some remarks on the notion of sparseness itself. From Proposition 2.2 we see that the problem of choosing a space of linear forms $f_1, \ldots, f_c \in I$ of given degree $d$ that are a homogeneous system of parameters modulo a homogeneous ideal $J$, is equivalent to the following geometric problem: given an algebraic set $X$ of dimension $c - 1$ in a projective space $\mathbb{P}^{m-1}$, find a linear subspace $L$ of codimension $c$ not meeting $X$. Equivalently, we may think of $L$ as coming from a linear subspace $M$ of an affine space $\mathbb{A}^{m}$, which is supposed to meet the cone over $X$ only in the origin.

We wish to choose $M$ to be as sparse as possible, relative to some given system of coordinates for $\mathbb{P}^{m-1}$. There are several possible definitions of sparseness, and they conflict with one another. In general, if we agree on a way to represent the space $M$, then we can speak of a space allowing the sparsest possible representation in this form. Perhaps the three most obvious representations are these: $M$ might be represented by the coordinates of a basis of $M$ (basis representation), by the coordinates of a basis for the space $M^\perp$ of linear functionals vanishing on $M$ (cobasis representation), or by Plücker coordinates, the maximal minors of some matrix representing the basis or dual basis (Plücker representation). In each case the number of nonzero coordinates is a measure of sparseness — we call them basis sparseness, cobasis sparseness, and Plücker sparseness respectively.

It is not hard to show that for 1-dimensional subspaces (and thus also for hyperplanes) the three measures of sparseness agree in the sense that all three choose the same space as the sparsest in a particular set of subspaces. But in general no two of these measures agree on naming the sparsest subspace, as may be seen from the following examples. In each case the subspace considered is the row space of the given matrix. As we will not make use of these facts, we leave their verification to the interested reader.

First, to show that Plücker sparseness does not agree with basis sparseness: The space $M_1$ represented by the matrix

$$M_1 \leftrightarrow \begin{pmatrix} 1 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 1 & 1 & 1 & 1 & 1 & 1 \end{pmatrix}$$

has basis sparseness 7 and Plücker sparseness 6, while the space $M_2$ represented by

$$M_2 \leftrightarrow \begin{pmatrix} 1 & 1 & 1 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 1 & 1 & 1 & 0 \end{pmatrix}$$
has basis sparseness 6 and Plücker sparseness 9.

The sparseness of a space \( M \) is the same as the cobasis sparseness of \( M^\perp \), so the spaces \( M^\perp_1 \) and \( M^\perp_2 \) illustrate the same point for cobasis sparseness.

It is harder to give examples in which basis sparseness and cobasis sparseness disagree, but the reader may check that if \( L_1 \) and \( L_2 \) are the 3-dimensional subspaces of a 9-dimensional vectorspace \( V \) represented by the matrices

\[
L_1 \leftrightarrow \begin{pmatrix}
1 & 1 & 1 & 1 & 1 & 1 & 1 & 1 & 1 \\
0 & 0 & 0 & 1 & 1 & 1 & 2 & 2 & 2 \\
0 & 1 & 2 & 0 & 1 & 2 & 10 & 11 & 12
\end{pmatrix}
\]

and

\[
L_2 \leftrightarrow \begin{pmatrix}
1 & 1 & 1 & 1 & 1 & 1 & 1 & 1 & 1 \\
0 & 0 & 0 & 1 & 1 & 1 & 2 & 3 & 4 \\
0 & 1 & 2 & 0 & 1 & 2 & 10 & 11 & 12
\end{pmatrix}
\]

then the basis sparseness of \( L_1 \) is \( 6 + 6 + 7 = 19 \), whereas that of \( L_2 \) is \( 6 + 6 + 6 = 18 \). The cobasis sparseness of each is \( 3 + 3 + 3 + 4 + 4 + 4 = 21 \). Now consider the subspaces

\[
M_3 = L_1 \oplus L_2^\perp \quad \text{and} \quad M_4 = L_2 \oplus L_1^\perp \quad \text{in} \quad V \oplus V^*.
\]

The basis sparsenesses of these spaces are \( 40 = 19 + 21 \) and \( 39 = 18 + 21 \) respectively. But as \( M_3^\perp = (L_1 \oplus L_2^\perp)^\perp = L_1^\perp \oplus L_2 \), and similarly for \( M_4 \), the cobasis sparsenesses for \( M_3 \) and \( M_4 \) are \( 39 = 18 + 21 \) and \( 40 = 19 + 21 \), reversing the order of the basis sparsenesses.

### Sparse Noether Normalization using Chow Forms

We now return to the problem of Noether Normalization. We will work in terms of basis sparseness of the space generated by the linear forms in the solution to the Normalization problem; our discussion can be adapted, by considering different expressions of the Chow form, to cobasis or Plücker sparseness as well. Let \( J \) be a homogeneous unmixed ideal in \( S \), and let \( X \) denote its projective variety in \( \mathbb{P}^{m-1} \). Changing notation somewhat, we suppose that \( X \) has degree \( p \) and dimension \( d - 1 \). We will show how to compute a Noether normalization consisting of linear forms

\[
f_i := c_{i1}x_1 + c_{i2}x_2 + \ldots + c_{im}x_m, \quad i = 1, 2, \ldots, d
\]

which is optimal in the sense that the number of non-zero coefficients \( c_{ij} \) is minimal — that is, the basis sparseness of the space spanned by the \( f_i \) is minimal. We call the number of nonzero \( c_{ij} \) the Noether complexity of \( X \).

Let \( R_X = R_X(c_{ij}) = R_X(f_1, \ldots, f_d) \) denote the Chow form of \( X \). This classical polynomial is characterized by the property that it vanishes if and only if the linear subspace defined by \( f_1(x) = \ldots = f_d(x) = 0 \) meets \( X \); see e.g. [Shafarevich 1977, §I.I.6.1]
and the references given in [Caniglia 1990]. The notation concerning Chow forms tends to vary from author to author. The specific notation to be employed here is taken from [Kapranov-Sturmfels-Zelevinsky 1992] and [Sturmfels 1993], namely, we express $R_X$ as a polynomial in brackets $[i_1 i_2 \ldots i_d]$, $1 \leq i_1 < \ldots < i_d \leq m$. These are the $d \times d$-minors of the $d \times m$-matrix $(c_{ij})$, or, equivalently, the Plücker coordinates of the codimension $k$ flat defined by (2.1). By Proposition 2.2, the Noether normalization problem for $R$ is equivalent to the problem of finding a non-root of the Chow form $R_X$.

**Example 2.4. (Hypersurfaces, $d = m - 1$)**

Suppose $J$ is the principal ideal generated by a homogeneous polynomial $F(x_1, x_2, \ldots, x_m)$, defining a hypersurface $X \subset \mathbb{P}^{m-1}$. In terms of brackets its Chow form equals

$$R_X = F([234\ldots m], [-134\ldots m], [124\ldots m], \ldots, (-1)^{m-1}[23\ldots m-1]).$$

(2.2)

The Noether normalizations of $X$ are precisely the $(m - 1) \times m$-matrices $(c_{ij})$ for which the bracket polynomial (2.2) does not vanish.

It is our objective to compute a $d \times m$-matrix $(c_{ij})$, which is a non-root of the Chow form $R_X$, and which is as sparse as possible with this property. Since $(c_{ij})$ must have maximal rank $d$, the Noether complexity of $X$ is at least $d = \text{dim}(X) + 1$. It is exactly $d$ if and only if $X$ is in Noether normal position with respect to some coordinate flat.

**Observation 2.5.** The coordinate forms $x_{i_1}, x_{i_2}, \ldots, x_{i_d}$ are a Noether normalization for $X$ if and only if the bracket power $[i_1 i_2 \ldots i_d]^p$ appears with non-zero coefficient in $R_X$.

Let $V = \{c_{ij} : 1 \leq i \leq d, 1 \leq j \leq m\}$ denote the set of variables. For any polynomial $f \in k[V]$ we define a simplicial complex $\Delta(f)$ as follows: A subset $W \subseteq V$ is a face of $\Delta(f)$ if and only if there exists a non-root of $f$ whose zero coordinates are precisely $W$. Equivalently, $W$ is not a face of $\Delta(f)$ whenever $f$ lies in the ideal generated by $W$. If we write $\text{supp}(m)$ for the set of variables dividing a monomial $m$, we see that the maximal faces of $\Delta(f)$ are the complements of the minimal sets of the form $\text{supp}(m)$ where $m$ is a monomial of $f$. In particular, for each monomial $m$, the complex $\Delta(m)$ is a simplex, consisting of all subsets of $V \setminus \text{supp}(m)$. Thus we get the first statement of the following:

**Lemma 2.6.** Let $f$ be a homogeneous polynomial in $k[V]$. Then $\Delta(f)$ is the union of the simplices $\Delta(m)$, where $m$ ranges over all monomials of $f$ with minimal support. Also, $\Delta(f)$ is the union of the simplices $\Delta(\text{in}_{\prec}(f))$, where $\prec$ ranges over all term orders on $k[V]$.

**Proof:** We have already proved the first statement. To prove the second it suffices to observe that because $f$ is homogeneous, every monomial of $f$ with minimal support is the initial monomial of $f$ with respect to some term order. ■

12
This lemma together with the above observations implies the following theorem.

**Theorem 2.7.** The Noether complexity of a projective variety \(X\) equals the least number of variables \(c_{ij}\) appearing in any initial monomial \(\operatorname{in}_\prec (R_X) = \prod c_{ij}^{\nu_{ij}}\) of its Chow form. 

**Example 2.3.** (continued) The reducible curve \(X \subset \mathbf{P}^5\) defined by \(J\) has Chow form

\[
R_X = [14] \cdot [15] \cdot [16] \cdot [26] \cdot [36] = (c_{11}c_{24} - c_{14}c_{21}) \cdot (c_{11}c_{25} - c_{15}c_{21}) \cdot (c_{11}c_{26} - c_{16}c_{21}) \cdot (c_{12}c_{26} - c_{16}c_{22}) \cdot (c_{13}c_{26} - c_{16}c_{23})
\]

The coefficient matrices of \(f_1, f_2\) and \(\tilde{f}_1, \tilde{f}_2\) considered above are seen to be non-roots of \(R_X\). The Noether complexity of the curve \(X\) is equal to six (cf. Theorem 2.7).

The most systematic approach to solving our problem would be to explicitly compute the Chow form \(R_X\). By the results of [Caniglia 1990], this can be done in single exponential time (in \(m\)). Theorem 2.7 implies that the Noether complexity and an optimal Noether normalization for \(X\) can be computed in single exponential time.

Unfortunately, this approach is not useful in practice, since the complete expansion of the Chow form into monomials \(\prod c_{ij}^{\nu_{ij}}\) is usually too big. Hence the Caniglia algorithm is only of theoretical interest with regard to our problem. In fact, the problem of computing the Noether complexity of a monomial ideal is NP-hard. The following proof of this fact has been pointed out to us by Jesus De Loera. Let \(G\) be any graph on \(V = \{x_1, \ldots, x_n\}\) and \(I_G\) the ideal generated by all square-free cubic monomials \(x_i x_j x_k\), and all \(x_i x_j\) not corresponding to an edge of \(G\) (this is the Stanley-Reisner ideal of \(G\) viewed as a simplicial complex). The Noether complexity of \(I_G\) equals the minimal number \(2n - |S_1| - |S_2|\), where \(S_1, S_2 \subset V\) ranges over all disjoint pairs of stable sets of \(G\). Here \(S_i\) indexes the zero entries in row \(i\) of a sparsest Noether normalization \((c_{ij})\). If we had a polynomial time algorithm for finding \(S_1\) and \(S_2\), then we could solve the NP-hard problem of computing a maximal stable set in any graph \(G_1\) as follows. Let \(G_2\) be a disjoint copy of \(G_1\), and let \(G\) be the graph obtained from their union union \(G_1 \cup G_2\) by connecting each vertex of \(G_1\) with each vertex of \(G_2\). Applying our algorithm to \(G\) we obtain a maximal stable set \(S_i\) for \(G = G_i, i = 1, 2\).

For practical computations we propose an approach using (truncated) Gröbner basis computations for the ideal \(J\). The following proposition, which is easily derived from the proof of Lemma 2.6, shows that the Noether complexity of a homogeneous ideal is bounded above by the Noether complexity of any of its initial ideals.

**Proposition 2.8.** Let \((c_{ij})\) be any Noether normalization of the initial monomial ideal \(\operatorname{in}_\omega (J)\), where \(\omega = (\omega_1, \ldots, \omega_n) \in \mathbf{Z}^m\) represents any term order for \(J\). Then, for almost all \(t \in k\), the matrix \((c_{ij} \cdot t^{\omega_j})\) is a Noether normalization of \(J\).

From this we get the following lifting algorithm: Choose any term order on \(S\), and compute a truncated Gröbner basis \(\{g_1, \ldots, g_r\}\) for \(J\), subject to the truncation condition
that the monomial ideal \( L = (in(f_1), \ldots, in(f_r)) \) has the same radical as \( in_\omega(J) \). Compute the Chow form \( R_L \) of \( L \), e.g., using method in Proposition 3.4 of [Sturmfels 1992]. The bracket monomial \( R_L \) has precisely the same bracket factors as \( R_{in(J)} \). We have

\[
\Delta(R_L) = \Delta(R_{in(J)}) \subseteq \Delta(R_X).
\] (2.3)

Choose any maximal face of the simplicial complex \( \Delta(R_M) \). This gives rise to a Noether normalization for \( in(J) \) and, using Proposition 2.8, we get a Noether normalization for \( J \).

In order to find a sparser Noether normalization we may repeat this procedure for as many different term orders as we can. In fact, whenever this is feasible, one might like to compute a universal Gröbner basis \( U \) for \( J \), that is, a finite subset of \( J \) which is a Gröbner basis simultaneously for all term orders on \( S \). From a universal Gröbner basis and the knowledge of the maximal faces of \( \Delta(R_M) \) we can read off the minimum of the Noether complexities of all initial ideals of \( J \). However, this minimum will generally not agree with the Noether complexity of \( J \), as the following example shows.

**Cautionary Example 2.9.** A homogeneous ideal \( J \) whose Noether complexity is smaller than the Noether complexity of any of its initial ideals \( in(J) \). Let \( m = 6 \) and consider

\[
J = (x_2x_5 - x_1x_6, x_3, x_4) \cap (x_1x_4 - x_3x_5, x_2, x_6) \cap (x_3x_6 - x_2x_4, x_1, x_5).
\]

The variety \( X \) of \( J \) is a union of three toric surfaces in \( P^5 \). Here the Chow form equals

\[
R_X = ([126][156] - [125][256]) \cdot ([135][345] - [145][134]) \cdot ([234][246] - [236][346]).
\]

The matrix

\[
(c_{ij}) = \begin{pmatrix}
1 & 0 & 0 & 1 & 0 & 0 \\
0 & 1 & 0 & 0 & 1 & 0 \\
0 & 0 & 1 & 0 & 0 & 1
\end{pmatrix}
\]

is a non-root of \( R_X \) and hence defines a Noether normalization. It is optimal because each term appearing in the complete expansion of \( R_X \) contains at least six of the variables \( c_{ij} \). This proves that the Noether complexity of \( X \) equals six.

The ideal \( J \) has six distinct initial ideals, each of which is isomorphic to

\[
in(J) = (x_2x_5, x_3, x_4) \cap (x_1x_4, x_2, x_6) \cap (x_2x_4, x_1, x_5).
\]

The complete expansion of the initial Chow form

\[
R_{in(J)} = [126][156][135][345][236][346]
\]

has 13,452 terms. Each of these terms contains at least eight variables. Hence the Noether complexity of each initial ideal of \( J \) equals eight. \( \blacksquare \)
