(Dated: August 1, 2011, preprint)

We report inelastic neutron scattering experiments on single crystals of Nd$_{1-x}$Sr$_x$MnO$_3$ with x=0.5 and x≈0.49. The spin-wave dispersion in the charge, orbital, and spin ordered state in Nd$_{0.5}$Sr$_{0.5}$MnO$_3$ exhibits a strongly anisotropic stiffness. The sign of the anisotropy is characteristic for the site-centered model for charge and orbital ordering in half-doped manganites. Within this model, linear spin-wave theory yields a perfect description of the experimental dispersion. In the ferromagnetic metallic state of Nd$_{1-x}$Sr$_x$MnO$_3$ with x≈0.49 and x=0.50 magnetic excitations exhibit nearly the same magnon dispersion. High intense signals near the zone-boundary over a wide energy level overlap with a sharp spin-wave dispersion which can be described with a Heisenberg model including nearest-neighbor interactions.

I. INTRODUCTION

In spite of its eminent relevance for colossal magnetoresistance (CMR) the exact nature of the charge, orbital and spin ordered (COSO) state in the manganites \( R_{1-x}A_x \text{MnO}_3 \) (\( R = \) rare earth, \( A = \) bivalent alkaline earth) with an antiferromagnetic insulating ground state is still under debate. The huge change in resistivity results from the competition between a ferromagnetic (FM) metallic and an antiferromagnetic (AFM) insulating state. A comprehensive understanding of the magnetic ordering is essential to get a wide understanding of CMR.

The parent compound LaMnO$_3$ with a transition-metal valence of Mn$^{3+}$ exhibits a ground state which is characterized by an antiferromagnetic A-type ordering.\(^1^{,}2\) The ratio of Mn$^{3+}$:Mn$^{4+}$ can be controlled by substitution of three-valent \( R \) with two-valent \( A \) leading to complex phase diagrams with a correlated charge, orbital, and spin ordered ground state (see Ref. 3 for a brief summary). In spite of the numerous publications in perovskite (113) manganites around half-doping, its COSO state has not been fully established.\(^3^{−}8\) Some 113-manganites around \( x=0.5 \) exhibit an A-type AFM metallic or FM metallic ground state while a decrease of the one-electron bandwidth leads to an AFM insulating state with CE-type ordering.\(^5\)

The COSO state in half-doped La$_{1-x}$Ca$_x$MnO$_3$ has been first studied by Wollan and Koehler and by Goodenough proposing a simple checkerboard ordering of Mn$^{3+}$ and Mn$^{4+}$ ions (Goodenough model).\(^9^{,}10\) Additionally, the \( e_g \) orbitals on Mn$^{3+}$ sites order in stripe-like patterns and spins order in an antiferromagnetic alignment called CE-type (see Fig. 1). The magnetic moments follow the orbital arrangement forming ferromagnetic zigzag chains while adjacent chains couple antiferromagnetically. First structural studies confirm the Goodenough model qualitatively, but the charge modulation appears to be significantly below the ideal value.\(^4^{,}11^{,}12\) Single-crystal neutron diffraction experiments on Pr$_{0.6}$Ca$_{0.4}$MnO$_3$ are not in agreement with the site-centered charge-ordering picture but propose charge order on the Mn-O-Mn bonds, forming Zener polaron (Zener-polaron model) yielding ferromagnetically coupled dimers.\(^13^{,}14\) The nature of the COSO state is thus still matter of debate and a clear proof for one of these models is still missing for \( R_{1-x}A_x \text{MnO}_3 \).

The magnetic exchange coupling follows the orbital...
occupations. Consequently a careful study of these interaction parameters by analyzing the spin-wave dispersion can give a direct view on the orbital arrangement. Indeed, for the single-layered (214) manganite La$_{0.5}$Sr$_{1.5}$MnO$_4$, inelastic neutron scattering experiments established the spin-wave dispersion yielding strong support for the COSO state described qualitatively by the Goodenough model.\textsuperscript{15} In the magnetic ground state, acoustical branches exhibit a steep spin-wave dispersion parallel to the zigzag chains and a flatten dispersion perpendicular to them. These observations indicate a strong coupling inside the zigzag chains and a weak coupling between adjacent chains as it is expected for the Goodenough model. On the contrary, the Zener-polaron model implies a strong ferromagnetic coupling between the dimers and hence an anisotropy opposite to the observations.

Perovskite manganites exhibit intrinsical twinning rendering microscopic investigations quite complex. The high-temperature structural phase transition associated with a lowering of the symmetry from cubic down to orthorhombic results in six different domain orientations.\textsuperscript{16} The occurrence of charge and orbital order can only enhance the number of different domains. The magnetic neutron scattering at a magnetic superstructure reflection in a twinned crystal is thus reduced by roughly a factor of six compared to a monodomain crystal. The same holds for the inelastic signal arising from a low-energy magnon. The interpretation of inelastic neutron scattering experiments is further aggravated by unavoidable superposition of the signals from different domain orientations at higher energy.

Due to the absence of twinning, the spin-wave dispersion and detailed studies in the COSO state has first been studied in single-layered manganites La$_{1-x}$Sr$_x$MnO$_4$.\textsuperscript{15,17–20} The $e_g$-orbitals in the undoped compound LaSrMnO$_4$ are dominantly aligned perpendicular to the planes, but upon doping in La$_{1-x}$Sr$_x$MnO$_4$ these $e_g$-orbitals flop into the MnO layers\textsuperscript{18}, so that the ground state of the 214-manganites around half-doping qualitatively resembles that in 113-manganites at low temperatures.\textsuperscript{21} There is thus strong support, that the qualitative CE-model describes the ground-state in single-layered half-doped La$_{0.5}$Sr$_{1.5}$MnO$_4$. However it remains an open issue whether the conventional AFM CE-type model may account for all COSO phases in manganites with $x \approx 0.5$, or whether the order essentially changes with the dimensionality (three-dimensional versus two-dimensional materials) and with the structural distortions associated with the bucking of the MnO layers. Furthermore, in spite of its charge and orbital ordered ground-state, single-layered manganites exhibit no CMR under moderate magnetic field most likely due to the enhanced stability of the COSO state in layered materials.\textsuperscript{22} Consequently, it is a matter of particular interest to extend the study of the spin-wave dispersion in the COSO state to perovskite manganites. There is a tremendous number of publications on magnetic excitations in the ferromagnetic metallic phase and in the A-type AFM phase in perovskite manganites.\textsuperscript{5,23–31} But best to our knowledge, investigations of the spin-wave dispersion in 113-manganites in the COSO state with AFM CE-type ordering are still missing. A microscopic analysis of both, the ferromagnetic metallic and the antiferromagnetic insulating state is important to understand the switching between these phases by external parameters like pressure, magnetic field or temperature.

In the paper we present experimental and theoretical analysis of the spin-wave dispersion in Nd$_{1-x}$Sr$_x$MnO$_3$ with $x=0.50$ and $x=0.49$. Antiferromagnetic CE-type ordering in Nd$_{1-x}$Sr$_x$MnO$_3$ has been shown to occur only in a very small doping range near $x=0.5$.\textsuperscript{8,32–33} A slight change of stoichiometry from $x=0.50$ to $x=0.49$ can lead to a ground-state in which ferromagnetic ordering and antiferromagnetic CE-type order coexist, while the ferromagnetic metallic (FMM) state above the COSO state is stable in a broader concentration range.\textsuperscript{32} The paper is divided as follows: After the experimental section we start by discussing the COSO state of the half-doped
compound $\text{Nd}_{0.5}\text{Sr}_{0.5}\text{MnO}_3$. We present experimental data of the spin-wave dispersion up to energies of about 12 meV and compare these results with linear spin-wave theory. In the second part we present inelastic scattering measurements in the FMM state of $\text{Nd}_{0.5}\text{Sr}_{0.5}\text{MnO}_3$ and of $\text{Nd}_{0.51}\text{Sr}_{0.49}\text{MnO}_3$ along the main-symmetry directions and give a description of the FM magnon dispersion by a simple Heisenberg model.

II. EXPERIMENTAL

Two large single crystals of $\text{Nd}_{1-x}\text{Sr}_x\text{MnO}_3$ with $x=0.49$ and $x=0.50$ have been grown by the floating zone method. The starting materials, $\text{Nd}_2\text{O}_3$, $\text{SrCO}_3$, and $\text{MnO}_2$ were preheated and mixed in appropriate stoichiometric proportions. After sintering for several times at $1000\,^\circ\text{C}$ and $1200\,^\circ\text{C}$ a cylindrical rod with 90 mm length and 10 mm diameter was pressed and heated at $1500\,^\circ\text{C}$. The apparatus used for crystal growth was the floating zone furnace (Crystal Systems Incorporated), equipped with four halogen lamps. The feed and seed rods were rotated in opposite directions at about 15 rpm. The molten zone was vertically moved at a rate of 2-3 mm/h in a pressure of pure oxygen atmosphere (2 bar). The high quality of the two samples has been checked by macroscopic and microscopic studies. Magnetization was measured by a SQUID magnetometer, electric resistivity by a standard four-contact method, and X-ray powder diffraction experiments were carried out on a D5000 Siemens diffractometer.

$\text{Nd}_{1-x}\text{Sr}_x\text{MnO}_3$ with $x=0.49$ and $x=0.50$ crystallizes in the orthorhombic unit-cell with space group $\text{Ibmm}$ and room-temperature lattice parameters of $a\approx\sqrt{2}\times a_p$, $b\approx\sqrt{2}\times a_p$, $c\approx2\times a_p$, where $a_p$ is the lattice parameter of the cubic perovskite. In the following we use the cubic notations with $a_p=3.84\,\text{Å}$ and hence the reciprocal-lattice vectors are given in reduced lattice units as $Q=(h,k,l)=\frac{2\pi}{a_p}(q_x,q_y,q_z)$. $\text{Nd}_{1-x}\text{Sr}_x\text{MnO}_3$ with $x=0.49$ and $x=0.50$ is a paramagnetic-insulator at room-temperature and undergoes a transition into a FMM ordered state below $T_C\approx250\,\text{K}$. Upon cooling a transition of first order from the FMM state into the COSO state can be observed.\textsuperscript{32,34,35}

All of our neutron scattering experiments have been performed at the Laboratoire Léon Brillouin in Saclay. Diffraction experiments were made using the 3T.1 diffractometer and the G4.3 spectrometer. Inelastic neutron data were collected with the 1T and 4F.2 spectrometers. The spectrometer 1T, installed on the thermal channel of the reactor, was used with a pyrolytic graphite (PG) monochromator and with a PG analyzer. To suppress higher harmonics two PG filters were installed and the final neutron energy was fixed at either $E_f=14.7\,\text{meV}$ or $E_f=8.04\,\text{meV}$. The cold three-axis spectrometer 4F.2 working with a PG double-monochromator was used with a Be-filter to suppress higher harmonics.

III. THE CHARGE, ORBITAL AND SPIN ORDERED STATE IN $\text{Nd}_{0.5}\text{Sr}_{0.5}\text{MnO}_3$

The ferromagnetic metallic and antiferromagnetic insulating states in our single-crystal of $\text{Nd}_{0.5}\text{Sr}_{0.5}\text{MnO}_3$ have been well characterized by macroscopic techniques and by diffraction experiments demonstrating the high quality of our sample. Measurements of electric resistivity as a function of temperature indicate a transition into a (half-)metallic state below $T_C=255\,\text{K}$ and simultaneously a rapid increase of magnetization points to ferromagnetic ordering [Fig. 2(a), (d)]. The transition into a charge, orbital and spin ordered state at $T_{CO}\approx160\,\text{K}$ is of the first order. Herby, the electrical resistivity exhibits a jump by more than three orders of magnitude and the magnetization vanishes. X-ray powder diffraction has been performed from $T=15\,\text{K}$ up to $T=850\,\text{K}$. The refinement of the data was carried out with the Rietveld method implemented in the FullProf suite.\textsuperscript{36} The best description of the data can be obtained with the space group $\text{Ibmm}$ for the studied temperature range. The symmetry reduction from the space group $\text{Pm3m}$ of an ideal undistorted perovskite to space group $\text{Ibmm}$ arises from tilting of $\text{MnO}_6$ octahedra around an axis parallel to the edges in the ab-planes. The orthorhombic distortion of the lattice parameters increases rapidly at $T=550\,\text{K}$ which can arise from an orbital ordering effect of $\text{Mn}^{3+}$ ions [Fig. 2(c)]. Upon cooling through the FMM phase transition, a slight increase of the orthorhombic c-axis with a shrinking of the a and b-axis is observed. It appears likely that upon entering the FMM state an enhancement of the in-plane metallicity an FM exchange is favored. An abrupt change of the lattice parameters during the transition into the COSO state indicates a sudden and strong structural change [Fig. 2(b)]. Temperature-dependent neutron diffraction experiments at the Bragg reflection $Q_{FM}=(1,0,0)$ prove ferromagnetic ordering between $T_{CO}<T<T_C$ which is in perfect agreement with our magnetization data [Fig. 2(e)]. Note, that the FM signal at $Q_{FM}=(1,0,0)$ is also visible above $T_C$, but it gets strongly suppressed in the COSO state. The temperature-dependent behavior of the superstructure reflection intensity of $Q_{Mn^{3+}}=(0.25,0.25,0.5)$ provides information on magnetic ordering of $\text{Mn}^{3+}$ below $T_{CO}$ [Fig. 2(e); for more details see Ref. 19]. The quality of our sample is evident from the observed sharp transitions, the increase in resistivity by several orders of magnitude, and from the perfect agreements of $T_C$ and $T_{CO}$ with published data.\textsuperscript{34,35} Although charge and orbital ordering cannot be directly detected by neutron diffraction, charge and orbital ordering leads to a characteristic distortions of the $\text{MnO}_6$-octahedra that are visible in neutron diffraction experiments due to the higher sensitivity to oxygen.

The Goodenough model predicts an alternating charge ordering of $\text{Mn}^{3+}$ and $\text{Mn}^{4+}$ ions. Considering an initially ideal cubic perovskite, this doubles the structural unit cell to $(\sqrt{2}a_p \times \sqrt{2}a_p \times a_p)$ and causes superstruc-
turance reflections with propagation vector $k_{oo}=(\pm \frac{1}{4}, \pm \frac{1}{2}, 0)$. Crystallographic studies find far smaller disproportion than a complete $\text{Mn}^{3+}/\text{Mn}^{4+}$ (see Ref. 11,12). Nevertheless we use the nominal labels $\text{Mn}^{3+}$ and $\text{Mn}^{4+}$ throughout this paper. The orbital ordering of $e_g$-electrons on $\text{Mn}^{3+}$-sites reduces the symmetry to orthorhombic with lattice parameters $2\sqrt{2}a_p$ along [1,1,0] and $\sqrt{2}a_p$ along [-1,1,0] for zigzag chains running along [1,1,0]. As the zigzag chains can propagate along [1,1,0] and [-1,1,0], orbital superstructure reflections with propagation vector $k_{oo}=(\pm \frac{1}{4}, \pm \frac{1}{2}, 0)$ can be detected. The orthorhombic distortion induces a twofold twinning since the orbitals can stack either along [1,1,0] or [-1,1,0] direction. Both arrangements superimpose and contribute to an equal amount in the scattering geometry studied in our sample. The superposition with the structural twinning in these pseudo-cubic compounds can lead to a very complex twinned structure in the COSO state. The charge and orbital ordering implies an antiferromagnetic CE-type ordering with ferromagnetic alignment of magnetic moments along the chains and antiferromagnetic coupling of adjacent chains. Fig. 1 shows a schematic representation of the charge, orbital and spin ordering with zigzag chains propagation in [1,1,0] direction. In perovskite manganites the planes of the orbital ordering always align with the structural distortions due to the octahedron tilting. The latter leads to an unit cell $\sqrt{2}a_t \times \sqrt{2}a_p \times 2d_p$ with the doubling being always perpendicular to the layers of orbital order (note that the zigzag chains run in these). Due to the strong structural distortion, orbitals and charges align in rows along this perpendicular direction (c-axis). Charge and orbital order are thus not modulated along this direction, corresponding to a ferro-type stacking. In the following the stacking direction is taken always along [0,0,1] in our cubic notation. The magnetic CE-type spin ordering results in two sublattices: the magnetic unit cell of $\text{Mn}^{4+}$ and the magnetic sublattice of $\text{Mn}^{3+}$. The latter one is depicted in Fig. 1. Superstructure reflections referring to the spin ordering of $\text{Mn}^{4+}$ can be detected at propagation vectors $k_{\text{Mn}^{4+}}=\pm(\frac{1}{2},0,\frac{1}{2})$ or $k_{\text{Mn}^{4+}}=\pm(0,\frac{1}{2},\frac{1}{2})$ and superstructure reflections referring to magnetic ordering of $\text{Mn}^{3+}$ at $k_{\text{Mn}^{3+}}=\pm(\frac{1}{4},\pm\frac{1}{4},\frac{1}{4})$. To investigate pure charge or orbital ordering we have to measure superstructure reflections with large $Q$ where magnetic order is negligible because the magnetic form-factor decreases rapidly with increasing scattering vector.

To study the spin-wave dispersion in the AFM ordered state along the main-symmetry directions, we aligned the sample in two different scattering-planes. Most of our experiments have been done by aligning the crystal in the (1,1,0)/(0,0,1) scattering plane to access momentum transfers of the kind (h,k,l). In order to focus on the spin-wave dispersion parallel to the zigzag chains the sample was orientated in a less conventional geometry with reflections (2,1,1)/(0,0,1) defining the scattering plane. The spin-wave dispersion at $T=12$ K, observed by inelastic neutron scattering from 2 meV up to about 12 meV is depicted in Fig. 3. The solid lines correspond to a fit based on linear spin-wave theory. Details on the theoretical calculations of the magnetic excitation spectrum are given below. Besides the superposition of all twins rendering the study at high energies impossible, we observe $Q$-independent signals around 0.9 meV and around 12 meV pointing to crystalline electric field (CEF) excitations of the Nd ions. Scans in different Brillouin zones and observations in similar compounds support this conclusion. Consequently clear magnetic excitations in all symmetry directions at 12 meV are not recordable. Our spin-wave studies have been performed around several antiferromagnetic zone centers, $\Gamma = (\frac{1}{4}, \frac{1}{4}, \pm \frac{1}{2})$ with $h,k$ odd integer, and have been com-

FIG. 3: (color online) Dispersion of the magnetic excitations in Nd$_{0.5}$Sr$_{0.5}$MnO$_3$ along the main-symmetry directions (a). The path $\Gamma$-$A$ stands for investigations in [1,0,0] direction (diagonal to the chains), while $\Gamma$-$B$ measures the dispersion perpendicular and $\Gamma$-$C$ parallel to the zigzag chains. In order to focus on the spin-wave dispersion parallel to the zigzag chains the sample was orientated in a less conventional geometry with reflections (2,1,1)/(0,0,1) defining the scattering plane. The spin-wave dispersion at $T=12$ K, observed by inelastic neutron scattering from 2 meV up to about 12 meV is depicted in Fig. 3. The solid lines correspond to a fit based on linear spin-wave theory. Details on the theoretical calculations of the magnetic excitation spectrum are given below. Besides the superposition of all twins rendering the study at high energies impossible, we observe $Q$-independent signals around 0.9 meV and around 12 meV pointing to crystalline electric field (CEF) excitations of the Nd ions. Scans in different Brillouin zones and observations in similar compounds support this conclusion. Consequently clear magnetic excitations in all symmetry directions at 12 meV are not recordable. Our spin-wave studies have been performed around several antiferromagnetic zone centers, $\Gamma = (\frac{1}{4}, \frac{1}{4}, \pm \frac{1}{2})$ with $h,k$ odd integer, and have been com-
bined to the presented dispersion. Fig. 4 shows examples of typical raw-data scans to study the spin-wave dispersion along the main-symmetry directions. We were able to separate between different paths since only one of the orbital twins contributes to a quarter-indexed magnetic zone center. For example, to measure the spin-wave perpendicular to the zigzag chains (Γ-B) starting at the zone center \((\frac{1}{2},\frac{1}{2},\frac{1}{2})\) one has to measure along the [-1,1,0] direction while the [1,1,0] direction measures the path parallel to the zigzag chains (Γ-A) and in c-direction (Γ-Z) are shown in (b)-(c). Solid lines correspond to fits with Gaussians.

The lowest acoustic branch along the path Γ-C exhibits a steeper dispersion than that along the path Γ-B. The endpoint of the acoustic branch at B can be observed at 7.5 meV. At this energy, we find the acoustic branch along Γ-C in the middle of the Brillouin zone pointing to a stronger ferromagnetic coupling parallel to the zigzag chains in comparison to the coupling perpendicular to the chains. Although magnetic excitations at the zone-boundary parallel to the chains can experimentally not be resolved due to the twinning, the anisotropic behavior is apparent. Our theoretical calculations predict a magnon energy of about 22 meV at the zone boundary which is three times larger than the endpoint B of the branch Γ-B. This study is in full agreement with the observations in La\(_{0.5}\)Sr\(_{1.5}\)MnO\(_4\) (Ref. 15). The antiferromagnetic coupling along the c-direction (Γ-Z) exhibits an intermediate dispersion: this means a steeper acoustic branch in comparison to the antiferromagnetic coupling in Γ-B, but flatter than the ferromagnetic coupling along the zigzag chains (Γ-C). Consequently the antiferromagnetic coupling between adjacent chains is weaker in comparison to the antiferromagnetic stacking in c-direction. This is fundamentally different in the layered materials, where there is no significant c-axis coupling. The CE-type order in Nd\(_{0.5}\)Sr\(_{0.5}\)MnO\(_3\) is thus - as expected - much more three-dimensional in nature, the AFM stacking in c-direction is stronger than the AFM coupling between zigzag chains in the ab-layers.

Theoretically, the formation of the CE-type superstructure close to half filling is understood in terms of the degenerate double-exchange (DDEX) model\(^6\)\(^,\)\(^1\)\(^4\)\(^,\)\(^4\)\(^3\)\(^,\)\(^4\)\(^4\). The \(t_2g\) electrons form local magnetic moments (core spins) which are coupled to the itinerant electrons of the degenerate \(e_g\) orbitals by a ferromagnetic interatomic Hund’s exchange \(J_H\). In the context of the manganites, the DDEX model can be greatly simplified since \(J_H\) is much larger than the electronic bandwidth and the super-exchange between core spins which are treated as classical. In the limit \(J_H \to \infty\), the itinerant electrons can move only in a ferromagnetic background. The complex CE superstructure is the result of the frustration between the electronic kinetic energy and the antiferromagnetic super-exchange between the core spins. In this phase, the electronic kinetic energy is directed along ferromagnetic zigzag chains which form because of a cooperative ordering of charge- and orbital degrees of freedom\(^1\)\(^5\).

Although, the DDEX model treated in the semiclassical approximation can explain the richness of the phase diagram\(^1\)\(^4\) and in particular account for the CE structure observed in the close vicinity of half filling\(^4\)\(^,\)\(^3\)\(^,\)\(^2\)\(^,\)\(^3\)\(^5\)\(^,\)\(^2\)\(^2\)\(^,\)\(^3\)\(^2\)\(^,\)\(^1\)\(^2\)\(^,\)\(^3\)\(^2\)\(^,\)\(^4\)\(^2\)\(^,\)\(^3\)\(^2\)\(^,\) the calculation of the magnetic excitation spectra within the DDEX model is extremely difficult since it requires finite \(J_H\) and quantum mechanical treatment of the core spins\(^4\)\(^,\)\(^3\)\(^4\). To avoid these complications, we compute the spectrum from a spin-only model with effective exchange couplings which includes both, AFM-super- and FM-double-exchange contributions. The latter are expected to contribute predominantly along the chains and to overcompensate the bare AFM super-exchange. Consequently, a minimal effective model consists of FM couplings \(J_{FM}\) along the chains and AFM couplings \(J_{AFM}\)
Indeed, the magnetic excitation spectrum of the layered system \( \text{La}_{0.5}\text{Sr}_{1.5}\text{MnO}_4 \) can be explained remarkably well by this minimal model. Including an additional next-nearest neighbor exchange \( J_{FM,2} \) between Mn\(^{4+}\) sites along the chains (Fig. 6) and a small single-ion anisotropy \( \Lambda \) to account for the spin gap, one finds an excellent description of the neutron scattering data even for optical branches at higher energies which has been interpreted as further evidence for the existence of the AFM CE-type superstructure at half filling.

In the following, we use exactly the same model to fit the spectrum of the perovskite \( \text{Nd}_{0.5}\text{Sr}_{0.5}\text{MnO}_4 \) including an additional coupling \( J_{AFM,c} \) along the \( c \) direction (Fig. 6). The effective spin-only Hamiltonian reads

\[
\hat{H} = -J_{FM} \sum_{\langle i,j \rangle} \hat{S}_i \cdot \hat{S}_j - J_{FM,2} \sum_{\langle\langle i,j \rangle\rangle} \hat{S}_i \cdot \hat{S}_j + J_{AFM} \sum_{\langle i,j \rangle} \hat{S}_i \cdot \hat{S}_j + J_{AFM,c} \sum_{\langle\langle i,j \rangle\rangle} \hat{S}_i \cdot \hat{S}_j + \Lambda \sum_i (\hat{S}_i^z)^2
\]

(1)

where the exchange couplings \( J_{FM}, J_{FM,2}, J_{AFM}, J_{AFM,c} \) and single-ion anisotropy \( \Lambda \) are defined to be positive. The sites on the three dimensional lattice are labelled by \( i \), \( \langle i \rangle_{||} \) and \( \langle\langle i \rangle \rangle \) denote nearest and next-nearest neighbor bonds along the FM zigzag chains. Note that \( J_{FM,2} \) acts only between Mn\(^{4+}\) spins on the corners of the chains. Nearest-neighbor bonds between the chains in the \( ab \)-plane and along the \( c \) direction are denoted by \( \langle i \rangle_{||} \) and \( \langle \langle i \rangle \rangle_c \), respectively. In order to facilitate the comparison with Ref. 15 we use the same definition of the sum: each bond appears only ones.

In the following, we use linear spin-wave theory to calculate the magnetic excitation spectrum and subsequently fit the experimental data. The procedure is standard and details can be found elsewhere. After representing the spins by Holstein-Primakoff bosons the spectrum is obtained by a Bogoliubov transformation which amounts to diagonalizing a 16 by 16 matrix which is explicitly given in Ref. [45] in the case \( J_{FM,2} = \Lambda = 0 \).

Whereas the idealized CE structure assumes a checkerboard ordering of Mn\(^{3+}\) and Mn\(^{4+}\) sites with corresponding local moment spins of \( S_1 = 2 \) and \( S_2 = 3/2 \), respectively, the experimentally observed charge and spin modulations are significantly smaller. To account for this, in the following we use \( S_1 = 1.79 \) and \( S_2 = 1.67 \) such that \( S_1S_2 = 3 \) and \( S_1/S_2 = 3/2.8 \) equal to the ratio of the measured moments.

The best fit parameters are summarized in Table I. As in the layered system,\(^{15} \) the FM coupling along the chains \( J_{FM} \) is found to be much larger than the AFM in-plane coupling \( J_{AFM} \) between the chains. For the \( \text{La}_{0.5}\text{Sr}_{1.5}\text{MnO}_4 \) compound we used for the spins of Mn\(^{3+}\) \( S_1 = 2 \) and for the spins of Mn\(^{4+}\) \( S_2 = 1.5 \). As the product of \( S_1S_2 = 3 \) is the same for both systems, the nearest-neighbor parameters \( J_{FM} \) and \( J_{AFM} \) can directly be compared.

This observation and the ratio \( J_{AFM,c}/J_{AFM} \approx 4 \) are in agreement with a quantitative estimate of the exchange couplings based on a modified Kanomori model which carefully takes details of the lattice structures of various CE-type manganites into account.\(^{47} \)

| \( J_{FM} \) [meV] | \( J_{FM,2} \) [meV] | \( J_{AFM} \) [meV] | \( J_{AFM,c} \) [meV] |
|-----------------|-----------------|-----------------|-----------------|
| \( \text{Nd}_{0.5}\text{Sr}_{0.5}\text{MnO}_4 \) | 6.76 | 2.76 | 0.75 |
| \( \text{La}_{0.5}\text{Sr}_{1.5}\text{MnO}_4 \) | 9.98 | 1.83 | 3.69 |
| \( \text{Nd}_{0.5}\text{Sr}_{0.5}\text{MnO}_4 \) | 3.22 | - | |

TABLE I: Results of the obtained fit parameters in the AFM CE-type state for \( \text{Nd}_{0.5}\text{Sr}_{0.5}\text{MnO}_4 \) in comparison to the fit parameters in \( \text{La}_{0.5}\text{Sr}_{1.5}\text{MnO}_4 \) from Ref. 15.

\( J_{AFM,c} \) connects either two Mn\(^{3+}\) or two Mn\(^{4+}\) sites, whereas \( J_{AFM} \) couples one Mn\(^{3+}\) and one Mn\(^{4+}\) site where imperfect orbital polarization will imply a FM double-exchange interaction rendering the AFM superexchange. As in addition the crystal lattice is considerably flattened, \( J_{AFM,c} \) is much larger than \( J_{AFM} \). In our model we include a simple single-ion anisotropy term \( \Lambda \sum_i (\hat{S}_i^z)^2 \). The ordered moments in the CE-type phase in \( \text{Nd}_{0.5}\text{Sr}_{0.5}\text{MnO}_4 \) are aligned along the ab-plane. Therefore an anisotropy term perfectly accounts for an ab-easy-plane system. However the spins seem to be well fixed also within the ab-layers causing a splitting in the zone-center magnon energies.\(^{29} \) The same situation is also found in single-layered \( \text{La}_{0.5}\text{Sr}_{1.5}\text{MnO}_4 \), where the lower excitation could be assigned to the in-plane anisotropy. Also in \( \text{Nd}_{0.5}\text{Sr}_{0.5}\text{MnO}_3 \) we may identify the lower excitation with the in-plane anisotropy. It costs more energy to rotate the spins into the c-direction. A full treatment for such complex anisotropy has been given for a simple...
AFM layered structure in Ref. 48.

Inelastic neutron scattering experiment have been able to determine the spin-wave excitations of Nd$_{0.5}$Sr$_{0.5}$MnO$_3$ for energies up to about 12 meV. Our data exhibit a steeper magnetic dispersion parallel to the zigzag chains while the dispersion perpendicular to the chains is flatten. This observation is in contrast to the Zener-polaron model which implies a strong coupling inside the dimers. Taking this and the magnetic structure of the Zener-polaron scenario into account one obtains just the opposite anisotropy in the dispersion slopes along the Γ-B and Γ-C directions studied here. The spin-wave theory within the CE-type structure explains perfectly our experimental data. The experimental and theoretical analysis are in agreement with the single-layered compound La$_{0.5}$Sr$_{1.5}$MnO$_4$ (Ref. 15). Consequently we may extend the strong support of the Goodenough model to perovskite manganes around half-doping.

IV. THE FERROMAGNETIC METALLIC STATE IN Nd$_{0.5}$Sr$_{0.5}$MnO$_3$

In order to analyze the competition between the insulating COSO and the FMM phases in Nd$_{0.5}$Sr$_{0.5}$MnO$_3$ we performed studies of the magnon dispersion in the FMM phase as well. The magnetic excitations in the FMM state in perovskite manganites have been studied in many different compounds and a damping of the spin-wave dispersion towards the zone boundaries have been reported in many cases. To explain this behavior, several microscopic mechanisms have been proposed, without reaching a clear conclusion (for a brief summary see Ref. 51). One explanation for the softening of the spin-wave dispersion might be the development of quantized spin-waves within ferromagnetic clusters of restricted sizes as reported in Ref. 27,31.

We studied the spin dynamics of Nd$_{0.5}$Sr$_{0.5}$MnO$_3$ at $T=174$ K, where the ferromagnetic signal of the reflection at $Q_{FM}=(1,0,0)$ exhibits its maximum [see Fig. 2(e)]. To investigate magnetic excitations along the main-symmetry directions [1,0,0], [0,1,1] and [1,1,1], we aligned the sample with reflections (1,0,0) and (0,1,1) defining the scattering plane. All data have been collected around the Bragg-reflections $Q_{FM}=(1,0,0)$, $Q_{FM}=(0,1,1)$ and $Q_{FM}=(1,1,1)$. Most data have been collected with the thermal spectrometer 1T with fixed $E_f=14.7$ meV. The calibration of the spectrometer has been checked by a Vanadium standard crystal. An energy scan with $E_f=14.7$ meV indicates a resolution of $\Delta E\approx$1 meV. Fig. 7 presents the spin-wave dispersion along the main symmetry directions. The data have been corrected by the Bose factor and finally fitted with the ResLib code which calculates the convolution of the four-dimensional resolution function with the dispersion.\textsuperscript{51} We were able to investigate magnetic excitations of the acoustic branch along the paths Γ-R, Γ-M, and Γ-X. An energy scan with the cold-source spectrometer 4F.2 at the zone-center $Q_{FM}=(1,0,0)$ yields no evidence for an excitation gap. Constant-energy scans around the ferromagnetic zone-center $Q_{FM}=(1,0,0)$ are depicted in Fig. 8(a). Investigations in different Brillouin zones clearly identify a mag-
netic origin for the signals appearing at low energy transfer, since the intensity follows the magnetic form factor as shown in Fig. 8(b). In Ref. 25 the spin-wave dispersion in the FMM state in Nd₈₀S₅₀MnO₃ along different symmetry directions has been studied and an extremely flat dispersion with energies around 10 meV at the zone boundaries is reported. Our experiments disagree with these observations since our data yield much steeper branches. For example, clear excitations along the [1,1,1] direction between energies of E=18 meV and E=22 meV can be observed in the middle of the Brillouin zone (see Fig. 9). The main magnetic signal seems to stem from the simple ferromagnetic magnon branch; but there are weak but significant additional signals which are most likely magnetic as well. The constant energy cuts (h,0,0) across the (1,0,0) FM Bragg-peak show more intensity near the magnetic zone boundaries ≈(0.5,0,0) than at the center which can not be attributed to the background. Also the energy scan at (1.5,0,0) exhibits significant intensity below the energy of the magnon branch [Fig. 7 (b)]. This scattering resembles the splitting of the magnon branches observed in La₉₆−ₓ(Ca,Sr)ₓMnO₃ at lower doping, which was attributed to a confinement. However, such confinement effect - if present - must be much weaker in this higher-doped Nd₈₀S₅₀MnO₃ material.

Spin-wave dispersion in 113-manganites with a large electron bandwidth and high Tₐ can be described by calculations with the conventional Heisenberg model including only the nearest-neighbor exchange interactions. In the following description of our data only the sharp signals into account without keeping the increasing intensity near the zone-boundaries in mind. To evaluate the spin-wave dispersion in Nd₈₀S₅₀MnO₃ we use two models: (1) we consider only the ferromagnetic coupling between nearest-neighbor interaction J₁, (2) nearest-neighbor interactions J₁ and forth-nearest interactions J₄ are taken into account.

The Hamiltonian of a Heisenberg ferromagnet can be written as:

\[ \hat{H} = -\sum_{ij} J_{ij} \mathbf{S}_i \mathbf{S}_j \]  

(2)

Herby J_{ij} describes the magnetic exchange coupling between two spins \( \mathbf{S}_i \) and \( \mathbf{S}_j \) at the position \( \mathbf{R}_i \) and \( \mathbf{R}_j \).

A finite energy gap near the zone-center can be controlled by \( \Delta \). Since we do not observe a finite gap for the \([1,0,0], [0,1,1]\) and \([1,1,1]\) directions, we will set \( \Delta \) equal to zero.

The simplest case with only nearest-neighbor J₁ interactions leads to the relation:

\[ E(\mathbf{q}) = \Delta + 4S J_1 \left[ 3 - \cos(q_a a) - \cos(q_b a) - \cos(q_c a) \right] \]  

(4)

Taking only J₁ into account, we can very well describe our experimental data (Fig. 7 solid lines). The fits of the data with only the nearest-neighbor interaction J₁ yield 2SJ₁=7.6(2) meV for the \([1,0,0]\), 2SJ₁=6.3(2) meV for the \([0,1,1]\) and 2SJ₁=7.2(2) meV for the \([1,1,1]\) direction. To compare an improvement of the description of the fit by introducing the coupling J₄ as suggested previously in Ref. 50, the dispersion for the \([1,0,0]\) direction takes the form [Fig. 11(b)]:

\[ E(\mathbf{q}) = \Delta + 4S J_1 \left[ (1 - \cos(2\pi q_a)) \right] + 4S J_4 \left[ (1 - \cos(4\pi q_a)) \right] \]  

(5)

The best fit to the data with nearest-neighbor and forth-nearest interaction interaction is depicted in Fig. 7 by the dotted lines. There is only little difference in the spin-wave dispersion of the two models in the energy range studied. Therefore our data give no support for a related 2SJ₄ parameter.

In the CE-type state we obtained the best fit to the data for the ferromagnetic coupling parallel to the chains with 2SJ₁₊₂M=11.7 meV. In the FM state we can describe the data with a mean exchange energy of 2SJ₁=7.0(5) meV for the fit with nearest-neighbor interaction taking into account. This means the nearest-neighbor ferromagnetic exchange in the FM state is strongly reduced by a factor of about 1.5 in comparison to the AFM CE-type state, but note that each spin has six ferromagnetically coupled spins in the FMM state, compared...
to only two FM neighbors in the CE-phases. In the single-layered compounds La_{0.5}Sr_{1.5}MnO_{4} an exchange energy of 2SJ_{FM}=7.5(5) meV has been observed above the AFM CE-type ordered state. Consequently, the exchange parameters in the FM states in La_{0.5}Sr_{1.5}MnO_{4} and in Nd_{0.5}Sr_{0.5}MnO_{3} are almost identical. This result is quite interesting since the single-layered compound does not show metallic behavior and possesses less neighbors. More importantly, the layered compound only exhibits ferromagnetic fluctuations generated by ferromagnetic clusters with finite size above T_{CO}. Our investigation in the FMM state in Nd_{0.5}Sr_{0.5}MnO_{3} indicate a quite good description of the data along the main-symmetry directions by taking only the nearest-neighbor coupling J_1 into account (but note that our model is slightly over-simplified since we do not take the intensities near the zone-boundary taking into account).

To get a more precise perception of the magnetic excitation in the FMM state in Nd_{1-x}Sr_{x}MnO_{3} and to compare the exchange parameters we decided to study the spin-wave dispersion in a slightly electron-doped single crystal with a composition of Nd_{0.51}Sr_{0.49}MnO_{3}.

V. THE FERROMAGNETIC METALLIC STATE IN Nd_{0.51}Sr_{0.49}MnO_{3}

A single-crystal of Nd_{1-x}Sr_{x}MnO_{3} with doping level x=0.49 has been characterized by temperature-dependent measurements of magnetization, resistivity, X-ray, neutron diffraction and by EDX analysis. A significant drop of resistivity accompanied by an increase of magnetization reminiscent of the FMM state is observed at T_{C}=245 K (Fig. 10). In accordance with the macroscopic studies, the scattering at Q_{FM}=(1,1,0) exhibits an increase of intensity below T_{C} which can be ascribed to ferromagnetic correlations [Fig. 10(c)]. Upon further cooling, the electric resistivity increases by more than two orders of magnitude at the first order transition into the COSO state at T_{CO}=112 K. Temperature-dependent

FIG. 9: (color online) Observed excitation at high energies along the symmetry direction [1,1,1]. The maximum shifts to increasing q with increasing energy indicating the steeper dispersion.

FIG. 10: (color online) Characterization of the single crystal Nd_{0.51}Sr_{0.49}MnO_{3} by macroscopic and microscopic studies. A ferromagnetic metallic state can be observed by electric resistivity measurements and magnetization data (a,c). Elastic neutron scattering at Q_{FM}=(1,1,0) confirms ferromagnetic ordering below T_{C} (d). A sudden increase in intensity of the superstructure reflection Q_{COO}=(2.25,0.25,0) below T_{CO} refers to orbital ordering (b),(d).

FIG. 11: (color online) Dispersion of the magnon excitation in the FMM state in Nd_{0.51}Sr_{0.49}MnO_{3} along the symmetry directions [1,0,0] and [0,1,1] at T=151 K (a). Solid lines refer to fits with only nearest-neighbor interactions J_1 and J_4 as depicted in (b).
investigations of the superstructure reflection referring to orbital ordering $Q_{OO} = (2.25, 0.25, 0)$ yield a sizeable signal below $T_{CO}$ [Fig. 10(d)]. Comparing the transition temperatures into the COSO state in Nd$_{1-x}$Sr$_x$MnO$_3$ for $x=0.50$ and $x=0.49$, we observe a less robust COSO state in Nd$_{0.51}$Sr$_{0.49}$MnO$_3$. Before discussing inelastic data we want to compare the ground state properties of the ideally doped system ($x=0.5$) in comparison to the slightly electron-doped system ($x=0.49$). In Nd$_{0.51}$Sr$_{0.49}$MnO$_3$ below $T \approx 50$ K, the electric resistivity is almost constant. In contrast, for $x=0.5$ we find a continuous increase of resistivity below $T_{CO}$ up to $\rho \approx 10^4$ $\Omega$m at the lowest temperature in comparison to $\rho \approx 10^0$ $\Omega$m for $x=0.49$. The slight doping difference between these two compounds strongly affects the magnetization at low temperatures as well. The magnetization with an applied field of $B=50$ mT saturates with $m=0.05$ $\mu_B$/Mn for $x=0.49$ while the magnetization for $x=0.50$ tends to zero at low temperatures. These properties underline the coexistence of antiferromagnetic CE-type and ferromagnetic ordering in the ground state of Nd$_{0.51}$Sr$_{0.49}$MnO$_3$ as reported in Ref. 32. Neutron diffraction of the reflection $Q_{FM} = (1, 0, 0)$ further supports this interpretation. The signal below $T_C$ increases as in the half-doped system, but in the COSO state in $x=0.49$ a high intensity can still be recorded at low temperature. We analyzed the stoichiometry of the samples with EDX analysis. However the accuracy of this method does not allow for determining the content of oxygen concentration. Hence we may not rule out an oxygen-deficiency. Concerning the various transition temperatures and the temperature dependence of the electrical resistivity our sample is fully comparable to the Nd$_{0.51}$Sr$_{0.49}$MnO$_3$ crystal studied in Ref. 32.

We have studied the spin-wave excitations in Nd$_{0.51}$Sr$_{0.49}$MnO$_3$ at $T=151$ K, which is well in the ferromagnetically ordered state, and present an analysis of the data with the same Heisenberg models as those used for the half-doped compound. The scattering experiments have been performed by aligning the crystal with the reflections $(1,0,0)/(0,1,1)$, allowing momentum transfers of the kind $(h,l,1)$. We focused our measurement on excitations along the symmetry directions $[1,0,0]$ and $[0,1,1]$ in cubic notation. Data have been measured in the Brillouin zones around the zone-centers $Q_{FM} = (1, 0, 0)$ and $Q_{FM} = (0,1,1)$ and were finally combined. The data have been corrected by the Bose factor and finally fitted with the convolution of the four-dimensional resolution function with the dispersion. Fits to the data results in the spin-wave dispersion as shown in Fig. 11. Raw-data scans with fixed energy around ferromagnetic zone centers along the $[1,0,0]$ and $[0,1,1]$ directions are depicted in Fig. 12.

In the following we will proof the experimental data of the sharp signals with the Heisenberg model as described for the half-doped system. The investigations of the dispersion near the zone center $\Gamma$ with the cold triple-axis spectrometer are in agreement with our observations in Nd$_{0.5}$Sr$_{0.5}$MnO$_3$ and we find no indication for a spin-wave gap in Nd$_{0.51}$Sr$_{0.49}$MnO$_3$. Consequently, we set $\Delta$ equal to zero in our calculation. To evaluate the spin-wave dispersion in Nd$_{0.51}$Sr$_{0.49}$MnO$_3$ we make the same assumptions as those used for the $x=0.5$ compound: (1) we consider only the ferromagnetic coupling between nearest-neighbor interaction $J_1$, and (2) nearest-neighbor interactions $J_1$ and forth-nearest interactions $J_4$ are taken into account.

All fit parameters for the spin-wave dispersion in Nd$_{0.51}$Sr$_{0.49}$MnO$_3$ and Nd$_{0.5}$Sr$_{0.5}$MnO$_3$ are summarized in Table II. Since no significant improvement of the reduced chi-squared $\chi^2_{red}$ for the model including $J_4$ and since the ratio of $J_4/J_1$ is quite small, there is no evidence that the forth-nearest-neighbors is needed to describe the ferromagnetic spin-wave dispersion in Nd$_{1-x}$Sr$_x$MnO$_3$ with $x=0.49$.

![FIG. 12: Raw-data scans with fixed energy observed in [1,0,0] direction. Data at 2 meV are taken with $E_F=8.05$ meV and above with $E_F=14.7$ meV. Intensities are normalized to same monitor but shifted as guide to the eyes (a). Signals along the symmetry direction [0,1,1] exhibit a loss in intensity and increase of width with increasing energy, too (b).](image)

| $x$     | $J_1$ [meV] | $J_2$ [meV] | $J_3$ [meV] | $J_4$ [%] |
|---------|-------------|-------------|-------------|-----------|
| 0.5     | 6.8(3)      | 6.5(3)      | 7.6(2)      | 6.3(2)    |
| 0.49    | 6.0(3)      | 4.9(2)      | 8.0(3)      | 5.3(9)    |
| 0.49    | 0.5(2)      | 0.8(1)      | -0.2(2)     | 0.4(4)    |

TABLE II: Fit parameters for the spin-wave dispersion in Nd$_{1-x}$Sr$_x$MnO$_3$ with $x=0.49$ and $x=0.50$ in the FMM state. The data have been obtained from two different models. Model 1, only nearest-neighbor interactions $J_1$ and model 2, nearest-neighbor interactions $J_1$ and forth-nearest interactions $J_4$ are taken into account.

Our studies for $x=0.49$ yield the identical dispersion in comparison to the optimal-doped compound $x=0.5$ in the FMM state. Near the zone-center the signal is sharp and resolution limited. One can easily notice that the intensity with increasing energy shrinks and the width starts to increase. Following the sharp excitations with increasing energy, toward the zone boundary the signal is hampered, similar to observations in the optimal doped compound $x=0.50$. 

The observation of nearly identical exchange parameters in Nd$_{1-x}$Sr$_x$MnO$_3$ with \(x=0.49\) and \(x=0.50\) again emphasizes an identical FMM state in \(x=0.49\) and \(x=0.50\). The FMM state in Nd$_{1-x}$Sr$_x$MnO$_3$ seems to be less sensitive to the doping than the COSO phase which is severely damaged by the small amount of holes in Nd$_{0.51}$Sr$_{0.49}$MnO$_3$.

VI. SUMMARY

In conclusion, we have studied the microscopic origin of the COSO state in Nd$_{0.5}$Sr$_{0.5}$MnO$_3$ and the FMM state in Nd$_{1-x}$Sr$_x$MnO$_3$ with \(x=0.50\) and \(x=0.49\) by inelastic neutron scattering. Despite the complications arising from the twinning in these perovskite manganites with pseudo-cubic structure, we were able to observe excitations along the main-symmetry directions up to \(E\approx 12\) meV in the AFM ground state of \(x=0.5\). We clearly find an anisotropic dispersion between the directions parallel and perpendicular to the orbital zigzag chains. Theoretical descriptions of the spin-wave dispersion by the AFM CE-type ordering perfectly describe our experimental data yielding results similar to the single-layered compound La$_{0.5}$Sr$_{1.5}$MnO$_4$ (Ref. 15). The good description of the experimental dispersion gives strong support for the qualitative CE-type Goodenough model. A model with bond-centered charge order is even unable to explain the sign of the anisotropy. Although the Zener-polaron picture cannot explain the data, a superposition of both, Goodenough model and Zener-polaron as suggested in Ref. 14 can not fully be excluded. The stacking of magnetic order along the c-direction, i.e. perpendicular to the planes of the zigzag chains, is rather strong. This finding can be understood by the flattening of the crystal structure and by the fact this stacking arises from strong Mn$^{3+}$-Mn$^{3+}$ and Mn$^{4+}$-Mn$^{4+}$ interactions.

The FMM state has been investigated in the half-doped compound Nd$_{0.5}$Sr$_{0.5}$MnO$_3$ and in the slightly electron-doped system Nd$_{0.51}$Sr$_{0.49}$MnO$_3$. Both concentrations exhibit nearly the same spin-wave spectra, proving that the FMM state is little affected by the slight difference in doping. In Nd$_{0.5}$Sr$_{0.5}$MnO$_3$ the magnon-dispersion along the main-symmetry-directions [1,0,0], [0,1,1] and [1,1,1] can be observed. The FMM state seems to consist of two parts; (1) a spin-wave dispersion which can be easily described with a Heisenberg model taking only nearest-neighbors interactions into account and (2) weak additional intensities near the zone boundaries over a wide energy band. The spin-wave dispersion in Nd$_{0.51}$Sr$_{0.49}$MnO$_3$ along the [1,0,0] and [0,1,1] directions exhibits identical results with a steep dispersion and damped excitations near the zone-boundary.
