Search for $CP$ violation at CLEO

David E. Jaffe*, University of California San Diego, La Jolla, CA 92093

Recent results from CLEO on the search for $CP$ violation in beauty and charm meson decays are reviewed.

$CP$ violation ($CPV$) was first observed nearly 40 years ago in the form of mixing-induced $CPV$ in neutral kaon decays [1]. With the the recent confirmation of the observation of direct $CP$ violation in neutral kaon decays [2], only $CPV$ due to the interference between mixing and decay remains to be observed. With the advent of the asymmetric B-factories, this phenomenon may soon be observed with a measurement of $\sin 2\beta$ [3–5]. The latter measurement has the advantage of a nearly unambiguous interpretation in terms of the description of weak decays in the standard model (SM).

CLEO has performed a number of searches for $CPV$ in beauty and charm meson decays. By and large the asymmetries expected in the SM are significantly smaller than the experimental precision so the results are primarily searches for physics beyond the SM.

The CLEO results for B mesons are based upon $9.7 \times 10^6 \; B\overline{B}$ pairs collected at the $\Upsilon(4S)$ resonance with the CLEOII ($3.3 \times 10^6 B\overline{B}$) and CLEOII.V ($6.4 \times 10^6 B\overline{B}$) detector configurations at the CESR symmetric $e^+e^-$ collider. The search for mixing and $CPV$ in neutral charm meson decays utilizes 9.0 fb$^{-1}$ of $e^+e^-$ collisions at $\sqrt{s} \approx 10.6$ GeV accumulated with the CLEOII.V configuration. The inner wire chamber and 3.5 cm radius beampipe of CLEOII [2] were replaced by a 2.0 cm radius beampipe and a three-layer, double-sided silicon vertex detector (SVX) to create CLEOII.V [6]. In addition the argon:ethane gas mixture in the main drift chamber was replaced by a helium:propane mixture. The resulting improvements in momentum and specific ionization ($dE/dx$) resolution permitted better separation of high momentum ($\sim 2.5$ GeV/$c$) charged kaons and pions. The SVX also permits the measurement of the proper decay time of neutral charm mesons that is essential for the study of $D^0\overline{D^0}$ mixing phenomena.

In the B system, CLEO has searched for evidence of direct $CPV$ through the measurements of rate asymmetries in charmless hadronic decays, radiative decays and in $B^\pm \rightarrow \psi(0)K^\pm$ decays. Almost all measurements rely on self-tagging decays with the charge of a $K^\pm$, $\pi^\pm$ or $K^{*\pm}$ identifying the B or $\overline{B}$ at decay. The branching fractions of a number of charmless hadronic decays observed by CLEO [6,7] are shown in Table 1. Table 1 also contains the preliminary results of the Belle [8,9] and BaBar [10] experiments confirming the CLEO results.

In the SM charmless hadronic B meson decays occur through $b \rightarrow u$ (“tree”) or $b \rightarrow s$ (“penguin”) transitions. The relatively large rate of $B \rightarrow K\pi$ with respect to $B \rightarrow \pi\pi$ indicates that the amplitudes for the tree ($A_T$) and penguin ($A_P$) contributions are comparable. Interference between the $b \rightarrow u$ and $b \rightarrow s$ processes make both the branching fractions ($\propto |A_P/A_T|\cos \gamma \cos \delta$) and rate asymmetries ($\propto |A_P/A_T|\sin \gamma \sin \delta$) sensitive to the weak mixing angle $\gamma \approx \arg(-V^*_{ub})$. The non-$CPV$ phase difference is $\delta$ and is frequently referred to as the “strong” phase. Based on the relative $B \rightarrow K\pi$ and $B \rightarrow \pi\pi$ rates, we have $|A_P/A_T| \sim 1/4$ while measurements of $|V_{cb}|$, $|V_{ub}|$, $\Delta m_d$, and $\epsilon_K$ indicate that $\gamma \sim 90^\circ$. Thus a large strong phase $|\sin \delta| \sim 1$ could produce rate asymmetries of $O(50\%)$ that would be observable with the current CLEO data.

CLEO utilizes the unbinned maximum likelihood (ML) method to achieve maximum precision

---

*Now at Brookhaven National Laboratory, Upton, NY 11973
on the charmless hadronic branching fractions. The ML technique utilizes the observables $\Delta E \equiv E(B) - E_{\text{beam}}$ and $M^2(B) \equiv E^2_{\text{beam}} - p^2(B)$ where $E(B)$ and $p(B)$ are the energy and momentum of the B candidate, respectively, $dE/dx$, the masses of intermediate resonances and the helicity angle of $B \to \text{vector}$, pseudoscalar decays where applicable. In addition event shape variables are combined in a Fisher discriminant that maximizes the separation between the “jetty” $e^+e^- \to q\bar{q}$ ($q = u,c,s,d$) background and the more spherical B decays. The likelihood is simultaneously maximized for the branching fraction $B \equiv \frac{1}{2}(B(\bar{B} \to f) + B(B \to f))$ and asymmetry $A_{CP} \equiv (B(\bar{B} \to f) - B(B \to f))/\sqrt{(B(\bar{B} \to f) + B(B \to f))}$ to obtain the results for the five decay modes shown in Table 1. All measured $A_{CP}$ are consistent with zero and with the prediction shown indicating that the strong phases are small for these decays. The precision of the measurements varies between 10% and 25% and is entirely dominated by statistics. Systematic checks show that no artificial asymmetries are introduced by either momentum or $dE/dx$ measurements at less than 1% based on studies of kinematically identified $K^\pm$ and $\pi^\pm$ from D decays.

Radiative B meson decays, in contrast to the charmless hadronic decays, are dominated by $b \to s\gamma$ transitions in the SM. This situation is quantified by the good agreement between the measured inclusive rate $B(b \to s\gamma)$ [14] and the next-to-leading order calculation [15] as shown in Table 2. Despite this agreement it is possible that non-SM propagators could produce significant asymmetry $O(40\%)$ in both inclusive and exclusive radiative B decays [16].

The search for $CPV$ in $B \to K^*\gamma$ decays utilizes the self-tagging $B^+ \to K^{*+}\gamma$ ($K^{*+} \to K^0\pi^+, K^+\pi^0$) and $B^0 \to K^{*0}\gamma$ ($K^{*0} \to K^+\pi^-$) decays. Only $\sim 60\%$ of the $B^0 \to K^{*0}\gamma$ candidates are amenable to self-tagging because the kinematic and $dE/dx$ identification of $K^{*0}$ and $\bar{K}^{*0}$ is ambiguous when $|p_K| \approx |p_{\pi}|$. Suppression of backgrounds from $e^+e^- \to q\bar{q}\gamma$ (initial state radiation) and $e^+e^- \to \pi^0X$ is accomplished by requirements on the angle of the $\gamma$ with respect to the $e^+e^-$ collision axis $|\cos\theta| < 0.71$ and by vetoing $\gamma$ consistent with a $\pi^0$ origin, respectively. Additional suppression of the jetty $q\bar{q}$ background is achieved by requirements on the angle between the $\gamma$ and the thrust axis [17] of the rest of the event excluding the B candidate. Asymmetries of $A_{CP} = -0.13 \pm 0.17$ and $+0.38 \pm 0.20$ for the signal and $-0.03 \pm 0.08$ and $+0.06 \pm 0.09$ for the background for neutral and charged $B \to K^*\gamma$ are determined from fits to the $M(B)$ distributions of B and $\bar{B}$ candidates shown in Figure 2. Assuming that $CPV$ would be independent of the light spectator quark $A_{CP}(B \to K^*\gamma) = +0.08 \pm 0.13$ $[+0.01 \pm 0.06]$ for the signal [background] where the uncertainty

The techniques used to measure the inclusive $b \to s\gamma$ branching fraction [14,21] have been adapted to measure $A_{CP}(b \to s\gamma)$. The B flavor is determined either by detecting a charged lepton from the semileptonic decay of the other B or by self-tagging through the “pseudo-reconstruction” of $X_s (X_s = K$ and $\leq 4\pi)$ with $X_s\gamma$ kinematically consistent with $B \to X_s\gamma$. The mistag rate for lepton tagging is 0.112 due almost entirely to $B^0\bar{B}^0$ mixing while the mistag rate for the pseudo-reconstruction is either 0.082 or 0.122 depending on the amount and quality of the particle identification information available. The preliminary measured asymmetry for the lepton tag (pseudo-reconstruction) is $A_{CP} = +0.155\pm0.147$ ($A_{CP} = -0.152\pm0.112$) where the uncertainty is statistical only. Studies revealed that asymmetries in lepton, $K$ and $\pi$ identification and reconstruction are $< 1\%$. Multiplicative uncertainties due to continuum $e^+e^-\to q\bar{q}$ and $b \to c$ background subtraction are $\sim 3\%$. The preliminary combined result with all corrections applied is $A_{CP} = (-0.063 \pm 0.090[s] \pm 0.022[a]) \times (1.00 \pm 0.03[m])$ where $s$, $a$ and $m$ denote the statistical, additive systematic and multiplicative systematic uncertainties, respectively, or $-0.22 < A_{CP} < +0.09$ at 90\% CL. This limit and the results for exclusive radiative decays exclude a significant fraction of the range allowed by non-SM processes but are still far from the $O(1\%)$ level predicted by the SM.
Table 2
Measured exclusive and inclusive branching fractions \((\times 10^{-5})\) for radiative \(B\) meson decays.

| Expt     | \(B^0 \to K^{0}\gamma\)          | \(B^+ \to K^+\gamma\)          | \(b \to s\gamma\)          |
|----------|----------------------------------|---------------------------------|----------------------------|
| Theory [15] | 4.55\(^{+0.72}_{-0.68}\) \pm 0.34 | 3.76\(^{+0.89}_{-0.83}\) \pm 0.28 | 32.8 \pm 3.3               |
| CLEO [17,18] | 4.94 \pm 0.93 \pm 0.55          | 2.81 \pm 1.20 \pm 0.40          | 31.5 \pm 3.5 \pm 2.6         |
| BELLE [18]     | 5.4 \pm 0.8 \pm 0.5            |                                 | 33.4 \pm 5.0 \pm 3.7 \pm 2.8 |

The final search for direct \(CPV\) is in \(B^{\pm} \to \psi^{(*)}K^{\pm}\) decays (\(\psi^{(*)}\) stands for \(J/\psi\) and \(\psi(2S)\)) that proceed by \(b \to c\bar{c}s\). The direct \(CPV\) asymmetry for these decays is expected to be very small because the sub-dominant penguin process (\(b \to s\bar{c}c\)) is suppressed and has nearly the same weak phase \(\arg(V_{cb}V_{cs}^*/V_{tb}V_{ts}) \approx \lambda^2\eta + \pi\) \((\lambda = 0.22, \eta \approx 1)\) as the dominant process. Non-SM effects could produce a noticeable asymmetry if there is an appreciable strong phase difference between the SM and non-SM amplitudes [22].

The quark process \(b \to c\bar{c}s\) is the same as that for the “golden mode” \(B^0 \to J/\psi K^0_S\) that is being used to measure \(\sin 2\beta\). An asymmetry in \(B^{\pm} \to \psi^{(*)}K^{\pm}\) decays, besides being evidence of non-SM physics, would indicate possible complications for the measurement of \(\sin 2\beta\) with \(B^0 \to J/\psi K^0_S\).

Experimentally \(B^{\pm} \to \psi^{(*)}K^{\pm}\) is nearly as background-free as \(B^0 \to \psi(2S)K^0_S\). The \(\psi^{(*)}\) are reconstructed in the \(\psi^{(*)} \to \ell^+\ell^-\) \((\ell = e, \mu)\) and \(\psi(2S) \to J/\psi \pi^+\pi^-\) modes. The charged kaon is identified kinematically to avoid any possible \(dE/dx\)-induced bias and \(B^{\pm} \to \psi^{(*)}K^{\pm}\) candidates are selected by requiring \(|\Delta E/\sigma(\Delta E)| < 3\) and \(|M(B) - M_{B^\pm}|/\sigma(M(B)) < 3\) as shown in Figure 3 where \(\sigma(x)\) is the candidate-by-candidate uncertainty in \(x\) as calculated from the covariance matrices of the reconstructed charged tracks. A small correction of \((+0.3 \pm 0.3)\)% is applied to the measured asymmetry to take into account the different cross-sections of \(K^+\) and \(K^-\) in the CLEO detector material. The asymmetries \(A_{CP}(J/\psi K^\pm) = (+1.8 \pm 4.3 \pm 0.4)\)% and \(A_{CP}(\psi(2S)K^\pm) = (+2.0 \pm 9.1 \pm 1.0)\)% are consistent with zero and are currently the most precise measurements of direct \(CPV\) in \(B\) meson decays [22].

In contrast to \(B\) decays, the CLEO II-V SVX permits measurement of the proper time dependence of charm meson decays [24] and enables the search for \(CPV\) and \(D^0\bar{D}^0\) mixing. \(D^0\bar{D}^0\) mixing is thought to be both GIM- and Cabibbo-suppressed in the SM although a wide range of predictions exists [23] and recent reevaluations indicate that the suppression may be only \(O(0.1\%)\) [26,27]. \(D^0\bar{D}^0\) mixing through either virtual or real intermediate states is quantified by the dimensionless parameters \(x \equiv \Delta m/\Gamma\) and \(y \equiv \Delta \Gamma/2\Gamma\), respectively, where \(\Delta m\) and \(\Delta \Gamma\) are the mass and width differences of the mass eigenstates and \(1/\Gamma\) is the average of the \(D^0\) and \(\bar{D}^0\) lifetimes. Non-SM effects could produce such signatures as \(|x| \gg |y|\) and/or large \(Im(x)/x\) (\(CPV\)). CLEO has searched for \(D^0\bar{D}^0\) mixing by comparing the rate of the “wrong sign” (WS) process \(D^0 \to K^+\pi^-\) with that of the “right sign” (RS) \(D^0 \to K^-\pi^+\) decay where the initial \(D^0\) is identified by the charge of the pion in the strong \(D^+ \to D^0\pi_{\text{slow}}\). For \(|x| \ll 1\) and \(\|y\| \ll 1\),
the proper time dependence of the WS rate is
\[ r_{ws}(t) = (R_D + \sqrt{R_D} y't + \frac{1}{4}(x'^2 + y'^2)t^2)e^{-t} \]  
(1)
in units of the D⁰ lifetime where \( R_D \) is the doubly-Cabibbo suppressed (DCS) rate, \( y' \equiv x \sin \delta - y \cos \delta \), \( x' \equiv x \cos \delta + y \sin \delta \), and \( \delta \) is a possible strong phase between the DCS and mixing amplitudes. The observation of a significant quadratic dependence in the proper time dependence of the WS rate would be an indication of mixing through \( x' \) or \( y' \) while a linear dependence would indicate mixing through \( y' \).

The WS rate is determined from a binned ML fit to the distribution of WS candidates in the \( Q \) vs \( M \) plane \( (M \equiv M(K\pi), Q \equiv M(K\pi_{\text{slow}}) - M - M_{\text{slow}}) \). The shapes of the four distinct backgrounds \( e^+e^- \rightarrow q\bar{q} (q = u,s,d), q\bar{q} \rightarrow c\bar{c}, D^0 \rightarrow \text{pseudoscalar}, \text{vector and } D^0 \rightarrow K^+\pi^- \) are taken from a simulated event sample corresponding to ten times the data luminosity. The signal shape is taken from the RS data which has measured resolutions of \( \sigma(Q) = 190 \pm 6 \text{ keV} \) and \( \sigma(M) = 6.4 \pm 0.1 \text{ MeV} \). The superb \( Q \) resolution is possible due to the SVX and is achieved by fitting the \( \pi^\pm_{\text{slow}} \) to the \( D^+ \) production point that is taken as the intersection of the beam spot and \( D^0 \) pseudotrack. A clear signal is visible in Figure 3 that shows the \( Q \) and \( M \) projections of the WS candidates when \( M \) and \( Q \) are required to be within \( 2\sigma \) of the known \( D^0 \) and \( D^+ \) energy release, respectively. The proper time distribution of the WS candidates within \( 2\sigma \) of the RS signal region \( M \) and \( Q \) is shown in Figure 3 along with a fit incorporating Eqn. \( 1 \) with the modifications \( R_D \rightarrow R_D(1 \pm A_D), x'[y'] \rightarrow x'[y'](1 \pm A_{x'y'}), \) and \( \delta \rightarrow \delta \pm \phi \) where \( +(-) \) corresponds to \( D^0(D^+) \) for direct \( CPV \), mixing-induced \( CPV \) and \( CPV \) due to the interference between mixing and decay, respectively. The fit prefers \( y' < 0 \) (destructive interference) but the mixing parameters \( y' \) and \( x' \) as well as the three \( CP \) violating parameters are all consistent with zero at 95% CL (Table 3).

Preliminary results of a similar analysis for the WS process \( D^0 \rightarrow K^+\pi^-\pi^0 \) reveal an excess of \( N_{WS} = 39^{+10}_{-9} \pm 7 \) candidates \( \delta \). Lack of knowledge of the WS resonant substructure (Dalitz plot) confounds the interpretation of this preliminary observation both for the relative WS to RS rate and for the proper time dependence. In essence each point in the Dalitz plot can have a different strong phase \( \delta \) thus complicating the interpretation via Eqn. \( 1 \) nonetheless, a significant \( t^2e^{-t} \) component in the proper time distribution would be evidence for \( D^0\bar{D}^0 \) mixing.

Finally, CLEO has searched for evidence of direct \( CPV \) in the Cabibbo-suppressed processes \( D^0 \rightarrow K^+K^- \) and \( D^0 \rightarrow \pi^+\pi^- \). The initial \( D^0 \) or \( \bar{D}^0 \) is tagged by the \( \pi^\pm_{\text{slow}} \) from \( D^*\pm \) decay and the \( D^0 \) and \( \bar{D}^0 \) rates are extracted from a fit to the \( Q \)-distribution with the signal shape taken from Cabibbo-favored \( D^0 \rightarrow K^-\pi^+ \) decays in data and the background shape taken from simulation. No reconstruction- or detector-induced asymmetry in the \( \pi^\pm_{\text{slow}} \) selection, \( A_{CP} = (+0.12 \pm 0.36)\% \), is observed as determined from \( K_S^0 \rightarrow \pi^+\pi^- \) decays. No significant \( CPV \) is observed \( A_{CP}(KK) = (0.04 \pm 2.18 \pm 0.84)\% \) and \( A_{CP}(\pi\pi) = (1.94 \pm 3.22 \pm 0.84)\% \) (preliminary). The systematic uncertainty from the background shape uncertainty is estimated to be 0.69% and the uncertainty due to \( \pi^\pm_{\text{slow}} \) selection is taken as 0.48%.

In summary no evidence for \( CPV \) has been observed by CLEO in beauty and charm meson decays with a precision of 4%-25% (beauty) and 2-3% (charm) which is dominated by the statistical uncertainty. Integrated luminosities approximately 100 times that accumulated by CLEO will be needed to attain a statistical precision comparable to the magnitude of direct \( CPV \) expected in the SM for beauty and charm decay of \( O(1\%) \) and \( O(0.1\%) \), respectively. The promising turn-on of the B-factories indicates that such data samples may be accumulated in approximately five years or less. Such measurements will then need to confront the potentially difficult task of measuring sub-percent detector- and reconstruction-induced asymmetries.

I would like to thank the conference organizers for an enjoyable and informative meeting in beautiful Ferrara. Thanks also to Jesse Ernst for comments on this contribution.
