We report an implementation of the constrained Random Phase Approximation (cRPA) method within the Projector Augmented-Wave framework. It allows for the calculation of the screened interaction in the same Wannier orbitals as our recent DFT+U and DFT+DMFT implementations. We present calculations of the dynamical Coulomb screened interaction in uranium dioxide and α and γ cerium on Wannier functions. We show that a self-consistent calculation of the static screened interaction in DFT+U together with a consistent Wannier basis is mandatory for γ cerium and uranium dioxide. We emphasize that a static approximation for the screened interaction in α cerium is too drastic.

I. INTRODUCTION

Because of the limited accuracy of available functionals, Density Functional Theory (DFT) fails for a large number of correlated systems. There are numerous examples for which DFT cannot describe neither their ground state properties, nor their excitation properties. Thus, in order to describe many-body effects arising in the strongly correlated systems containing for instance transition elements or f electrons, theories were designed to take into account the interaction among correlated orbitals explicitly. The DFT+U method or the combination of DFT with Dynamical Mean Field Theory method (DFT+DMFT) have been successfully applied to a large number of systems in the last twenty years. In particular, these methods have been particularly useful to study the ground state and the photoemission spectra of Mott insulators such as bulk actinides and lanthanide oxides. For instance, to date DFT+DMFT is the only method to give a good description of photoemission spectra of both α and γ cerium. However, in these frameworks and applications, the interaction among correlated orbitals, named U, remained most often an input parameter.

As a consequence, there is a stringent need to calculate the magnitude of the interaction U, in order to recover a truly ab initio scheme. Methods were then proposed to evaluate U from first-principles. The constrained Local Density Approximation (cLDA) method deduces the value of U from the variation of energy with respect to the number of correlated electrons on an atom. Later, Cococcioni et al generalized this method to a non basis dependent scheme. Finally, the constrained RPA method uses the linear response theory to compute the value of the screened interaction. Screening processes corresponding to electron hole transitions among the correlated orbitals are however excluded from the calculation. Indeed an exact many-body scheme would already contain all the screening processes associated to the degrees of freedom involved in the calculation. Therefore, some transitions have to be disregarded to avoid double-counting. The cRPA scheme very clearly defines which screening processes have to be taken into account. The method has been implemented in several electronic structure codes using the LMTO, FLAPW, FPLMTO, and Projector Augmented-Wave methods and applied to different systems in the last few years. An important point emphasized in several works is that the calculation of the cRPA screened interaction based on a previous DFT calculation depends crucially on the definition of a many-body model.

The many-body model is defined by a set of local orbitals together with the interactions among them. A cRPA calculation of a model would require first the definition of a set of local orbitals, and second a consistently calculated screened interaction. Whereas the choice of the angular momenta of the selected orbitals unambiguously defines the angular part of the local orbitals, the definition of the radial part is more subject to variation. Generally, it relies on the use of localized Wannier functions, which are built as a unitary transform of Kohn-Sham orbitals in an energy window. The key point is to construct the model specific cRPA screened interaction.

It is especially important to study this dependence as a function of the localization of the Wannier orbitals. Indeed, correlated orbitals used in DFT+U and DFT+DMFT can be formulated as Wannier orbitals with different energy windows depending on implementation choices. Thus the coherence of the DFT+U/DFT+DMFT calculations and of the cRPA calculation can only be guaranteed if both methods use the same Wannier functions. Implementations of DFT+U in popular codes very often use atomic orbitals, whereas implementations of DFT+DMFT use Wannier functions. It is thus expected that the value
of $U$ used in DFT+$U$ and DFT+DMFT should differ. Some works indeed discuss the calculation of $U$ for a given energy window, but there are no calculation of a screened interaction in the same basis as the one used in DFT+$U$ codes. Even for DFT+DMFT calculation, the definition of an energy window is especially important for systems with entangled correlated bands.

Moreover and especially for very localized systems — such as Mott insulators —, self-consistent calculations over $U$ are desirable because the erroneous LDA or Generalized Gradient Approximation (GGA) band structures cannot correctly describe the screening in these systems. The coherence of basis between the DFT+$U$ and the cRPA calculation is then of the utmost importance. This is in particular the case for cerium and uranium dioxide for which no self-consistent calculations of $U$ exist.

In this work, we report an implementation of the cRPA method using the PAW method in the ABINIT package. The implementation is versatile enough to allow for the calculation of screened interaction in both the same Wannier basis as our recent DFT+DMFT implementation and in atomic orbitals and as in our DFT+$U$ implementation. Then, we show that the self-consistent DFT+$U$ calculation of the screened interaction in the cRPA method in strongly correlated systems is essential to describe the static and dynamical screened interaction. We exemplify our study with two important applications: UO$_2$ and cerium.

II. THE CONSTRAINED RPA METHOD

As the cRPA method is described in details elsewhere, we only sketch the most important points here.

The screened interaction is in general a four index matrix that is defined as

$$U^\sigma_{\mathbf{m}_1,\mathbf{m}_2,\mathbf{m}_3,\mathbf{m}_4}(\omega) = \langle m_1^\sigma m_2^\sigma | \varepsilon_r^{-1}(\omega) | m_3^\sigma m_4^\sigma \rangle$$

with $\varepsilon_r$ the bare Coulomb interaction and $m_1, m_2, m_3, m_4$ the indices of the correlated orbitals.

In this work, the use Projected Wannier functions as defined in Refs. and similar Wannier functions have been used in cRPA calculations. We first introduce the auxiliary wavefunctions $|\tilde{\chi}^R_{\mathbf{k}\nu}\rangle$ as

$$|\tilde{\chi}^R_{\mathbf{k}\nu}\rangle \equiv \sum_{\mathbf{R} \in W} |\Psi^\nu_{\mathbf{R}\mathbf{k}}\rangle \langle \Psi^\nu_{\mathbf{R}\mathbf{k}} | \chi^\mathbf{R}_{\mathbf{k}\nu} \rangle.$$  

For a given atomic site $\mathbf{R}$, we call $|\chi^\mathbf{R}_{\mathbf{k}\nu}\rangle$ the Bloch transform of isolated atom Kohn Sham orbitals with projected angular momentum $m$. $|\Psi^\nu_{\mathbf{R}\mathbf{k}}\rangle$ are Kohn-Sham orbitals for k-point $\mathbf{k}$, band index $\nu$ and spin $\sigma$. $|\tilde{\chi}^R_{\mathbf{k}\nu}\rangle$ is thus a weighted sum of Kohn-Sham orbitals. This sum extends over a given number of Kohn Sham orbitals that can be defined by an index range or alternatively by an energy window $W$. The orthonormalization of $|\tilde{\chi}^R_{\mathbf{k}\nu}\rangle$ leads to well defined Wannier functions $|\tilde{\chi}^R_{\mathbf{k}\nu}\rangle$, unitarily related to $|\Psi^\nu_{\mathbf{R}\mathbf{k}}\rangle$. In the limit of a large number of Kohn Sham bands, the projection in Eq. becomes complete and the Wannier functions $|\tilde{\chi}^R_{\mathbf{k}\nu}\rangle$ become equivalent to atomic orbitals $|\chi^R_{\mathbf{k}\nu}\rangle$.

The definition of $U$ is very much similar to the Coulomb integrals used in quantum chemistry, but with the screening of the frequency dependent cRPA dielectric matrix, $\varepsilon_r(\omega)$. This dielectric matrix can be expressed as a function of the cRPA non-interacting polarizability $\chi^0_0(\omega)$ and the bare interaction $v$ as (in the matrix notation)

$$\varepsilon_r(\omega) = 1 - v \chi^0_0(\omega).$$

$\chi^0_0$ contains all electron-hole screening processes except the ones that are internal to the correlated orbitals of the model. It can be conveniently written as

$$\chi^0_0(\mathbf{r}, \mathbf{r}', \omega) = \sum_{\mathbf{k}, \mathbf{k}', \mathbf{n}, \sigma} \psi^\sigma_{\mathbf{n}\mathbf{k}}(\mathbf{r}) \psi^\sigma_{\mathbf{n}\mathbf{k}}^*(\mathbf{r}) \psi^\sigma_{\mathbf{n}\mathbf{k}'}(\mathbf{r}') \psi^\sigma_{\mathbf{n}\mathbf{k}'}^*(\mathbf{r}') \times w(\mathbf{k}, \mathbf{k}', \mathbf{n}, \mathbf{n}', \sigma) \frac{f^\sigma_{\mathbf{n}\mathbf{k}} - f^\sigma_{\mathbf{n}\mathbf{k}'}}{\epsilon^\sigma_{\mathbf{n}\mathbf{k}} - \epsilon^\sigma_{\mathbf{n}\mathbf{k}'} + \omega + i\delta}. \tag{4}$$

In Eq. $\mathbf{n}, \mathbf{n}'$ are band indices, $\mathbf{k}, \mathbf{k}'$ are k-points in the Brillouin Zone and $f_{\mathbf{n}\mathbf{k}}$ is the occupation number for band $\mathbf{n}$, spin $\sigma$ and k-point $\mathbf{k}$.

If the correlated bands in the model are completely isolated from the others, then we can assume that

$$w(\mathbf{k}, \mathbf{k}', \mathbf{n}, \mathbf{n}', \sigma) = 0 \tag{5}$$

when $(\mathbf{n}\mathbf{k})$ and $(\mathbf{n}'\mathbf{k}')$ are both correlated bands and $w = 1$ otherwise. For example, a model could define correlated orbitals as Wannier orbitals constructed only from the $f$ bands. Nevertheless, with this specific choice, the Wannier orbitals have some weight on other orbitals: Oxygen-$p$ for oxides or $spd$ for pure metals. The intensity of this weight depends on the hybridization of $f$ orbitals with the other orbitals. This last definition of correlated orbitals is not the one used in most implementations of DFT+$U$ in modern codes. In these implementations, correlated orbitals are most often atomic orbitals which thus corresponds to Wannier functions $|\tilde{\chi}^R_{\mathbf{k}\nu}\rangle$ for a large window of energy.

If the bands are completely entangled or if one defines Wannier functions $|\tilde{\chi}^R_{\mathbf{k}\nu}\rangle$ from a larger energy window, then the preceding assumption of $\chi^0_0(\omega)$ cannot be made and some authors have proposed the more general assumption

$$w(\mathbf{k}, \mathbf{k}', \mathbf{n}, \mathbf{n}', \sigma) = 1 - \sum_{\mathbf{m}_1} \frac{|\langle \psi^\sigma_{\mathbf{n}\mathbf{k}} | W^\sigma_{\mathbf{m}_1\mathbf{k}} \rangle|^2}{\sum_{\mathbf{m}_2} |\langle \psi^\sigma_{\mathbf{n}\mathbf{k}} | W^\sigma_{\mathbf{m}_2\mathbf{k}} \rangle|^2}. \tag{6}$$

If the correlated bands are not entangled and if the Wannier functions are defined from these correlated bands
only, then Eq. (6) simply reduces to Eq. (5). Fully screened coulomb interaction \( W \) corresponds to \( w = 1 \).

In this work, we use an implementation of the calculation of the dielectric function in PAW.\(^{49-51,53}\) From the screened interaction expressed in the Kohn Sham basis, we compute the screened interaction in Eq. (1), using the Wannier functions as defined in Refs. 39 and 11. The weight of Wannier functions necessary for Eq. (6) is evaluated within PAW following Ref. 39.

Then, the values of the famous Hubbard \( U \) and Hund \( J \) are simply extracted by taking the average among the considered localized orbitals:

\[
U = \frac{1}{4} \sum_{\sigma, \sigma'} \frac{1}{(2l + 1)^2} \sum_{m_1 = 1}^{2l + 1} \sum_{m_2 = 1}^{2l + 1} U_{m_1, m_2, m_1, m_2}^{\sigma, \sigma'}
\]

\[
J = \frac{1}{4} \sum_{\sigma, \sigma'} \frac{1}{(2l + 1)(2l + 2)} \sum_{m_1 = 1}^{2l + 1} \sum_{m_2 = 1}^{2l + 1} U_{m_1, m_2, m_2, m_1}^{\sigma, \sigma'}
\]

Note that this definition of \( U \) is also sometimes referred to as the F\(^3\) Slater integral. We emphasize that this definition is different from the average of the diagonal elements of the Coulomb interaction matrix \( U_{\text{diag}} \) = \( \frac{1}{2} \sum_{2l + 1} \sum_{m_1 = 1}^{2l + 1} U_{m_1, m_1, m_1, m_1}^{\sigma, \sigma'} \) (see e.g Ref. 31). In particular diagonal elements are usually larger, and thus \( U_{\text{diag}} \) > \( U \). However our definition is coherent with the \( U \) used in the DFT+\( U \) approach\(^{34}\) and physically describes the average interaction between electrons in all orbitals.

Appendix A gives the details of the implementation and the peculiarities of the PAW formalism for the calculation of \( U \). Appendix B gives a benchmark of our implementation with respect to recent calculations on SrVO\(_3\).

### III. COMPUTATIONAL DETAILS

The calculation are performed within the Projector Augmented-Wave (PAW) method as implemented in ABINIT\(^{48,50}\). The valence states include 2s, 2p for oxygen, 5s, 5p, 4f, 6s, 6p, 5d for cerium and 6s, 6p, 5f, 6s, 6d for uranium respectively. Two projectors per angular momentum are used, and completeness of the projector basis is checked by increasing their number. The parameters of calculation are chosen such that the precision on the static values of \( U \) and \( J \) is better than 0.2 eV. For UO\(_2\), we thus use a 4x4x4 k-point grid, and energy cutoffs for the wavefunctions, the dielectric function and the bare Coulomb interaction are respectively 15 Ha, 5 Ha, and 35 Ha. 100 bands are sufficient for the calculation of the polarisability. For cerium, we use a 8x8x8 k-point grid and energy cutoffs for the wavefunction, the dielectric function and the bare Coulomb interaction are respectively 15 Ha, 10 Ha and 35 Ha (for large values of the volume, a 4x4x4 k-point grid was sufficient). For the static screened exchange \( J \) in cerium, a value of 120 Ha was however necessary but a 4x4x4 k-point grid is sufficient as well as 100 bands for the calculation of the polarisability. This high value of the cutoff originates from the calculation of oscillator matrix elements in the PAW formalism (see appendix A). A smearing of the Kohn Sham occupations of 0.1 eV is used. For all systems, experimental structural parameters are used: 5.47 Å for UO\(_2\), 4.83 Å for α cerium, and 5.16 Å for γ cerium.

Unless specified, all DFT+\( U \) calculations use the Full Localized Limit (FLL) double counting correction\(^{34}\). A discussion on the role of the double counting correction is given in appendix C. For UO\(_2\), DFT+\( U \) are performed for simplicity in the ferromagnetic configuration, which requires a symmetry breaking\(^{35}\) and we use the correlated \( f \) density matrix found in Ref. 9.

### IV. DEFINITION OF THE MODELS FOR URANIUM DIOXIDE AND CERIUM

The goal of this section is to define models of correlation for uranium dioxide and cerium. For each model, one thus defines an energy window — that encompasses at least the bands which have the same main character as the selected orbitals. From the definition of the window energy, Wannier functions of the correlated orbitals are built according to the scheme of Ref. 39. From the choice of the correlated orbitals, the cRPA polarisability is built by excluding some screening channels corresponding to correlated orbitals. We distinguish different ways to exclude the screening according to Eq. (6) or to Eq. (5).

#### A. UO\(_2\)

Figure 1 represents the LDA band structure of UO\(_2\). The Op-like bands are located below the Fermi level in the energy window [-8 eV, -4 eV]. Near the Fermi level, bands have mainly a \( U \) \( f \) character and are non entangled in this LDA non magnetic calculation. As a consequence, one can define several models following the literature\(^{35}\). 

![Figure 1. UO\(_2\) band structure for the DFT-LDA non magnetic solution. The Fermi level is set to zero. The width of the bands (in red) is proportional to the amplitude of the \( f \) character for each band.](image-url)
as listed below. We give their energy window and screening channel excluded from the polarizability in Tab. I

\[ f \] model: The model is built from the $Uf$-like bands only.

\[ fp \] model: The model is built from the $Uf$-like and $Op$-like bands.

\[ f - fp \] model (a): As in the $fp$ model, Wannier functions are built from the $Uf$-like and $Op$-like bands. However, only the $f$ bands transitions are removed from the polarizability, using Eq. (5). It is equivalent to say that the constrained polarizability is built from $Eq. \ (6)$ with Wannier orbitals constructed from $Uf$-like bands only. Thus from an \textit{ab initio} point of view, this scheme is not coherent.

\[ f - fp \] model (b): Wannier functions are also built from the $Uf$-like and $Op$-like bands. Nevertheless, in this case, the cRPA polarizability is computed using $Eq. \ (5)$ in $Eq. \ (6)$. This is a more general way of doing because it is applicable to any system, even when bands are entangled. Furthermore the Wannier functions and the cRPA polarizability are here consistently defined.

\[ f\text{-}ext \] model (b): The same as $f - fp$ model (b) but Wannier functions are defined with more extended window of energy that are precised in Tab. I.

B. Cerium

The LDA band structure of $\gamma$ cerium is given in Fig. 2. One can see that the $f$ bands are largely entangled with $s$, $p$, and $d$ bands. The $f$, $fp$ and $f - fp$ (a) models we defined for UO$_2$ cannot be applied here. We give in Tab. II the list of models that we will use in the next section.

The four models $f\text{-}ext \ (b_1) \ (b_2) \ (b_3) \ (b_4)$ use a fixed number of bands (respectively 20, 30, 40 and 50) that corresponds to the energy windows given. The $f-(W_1)$ models are built to select an energy window $W_1$ to remove the $f$ bands contribution approximately in the polarizability. The $fd_{t_{2g}}$-ext model uses Wannier functions constructed from the specified energy window and the excluded bands for the polarisability are the $f$ and $d_{t_{2g}}$ bands. In this last model, as all bands are entangled, we choose to remove the 7 $f$ bands and the 3 bands that are located just above as they are mainly of $d_{e_g}$ character and are lower in energy than the $d_{e_g}$ orbitals.

V. UO$_2$: RESULTS AND DISCUSSION

In this section, we present the static and dynamical cRPA screened interaction in uranium dioxide. The third subsection is devoted to the self-consistent calculation of the static screened interaction.

| Models | Excluded Wannier functions |
|--------|-----------------------------|
|        | screening channels defined corresponding with bands energy window (eV) |
| $f$    | $f$ [1, 1.7] |
| $fp$   | $f$, $O$- $f$, $O$- [8, 1.7] |
| $f - fp$ (a) | $f$, $O$- $f$, $O$- [8, 1.7] |
| $f - fp$ (b) | $f$, Wannier weight $f$, $O$- [8, 1.7] |
| $f\text{-}ext \ (b_a)$ | $f$, Wannier weight 5-28 [8, 17.0] |
| $f\text{-}ext \ (b_b)$ | $f$, Wannier weight 5-38 [8, 30.0] |
| $f\text{-}ext \ (b_c)$ | $f$, Wannier weight 5-48 [8, 40.0] |

TABLE I. Different models for the description of correlation in UO$_2$. From the top to the bottom, the $f$ Wannier function are expected to be more and more localized. For the first three model (resp last four models), $Eq. (5)$ (resp $Eq. (6)$) is used to compute $\chi_0$. The three models $f\text{-}ext \ (b_a) \ (b_b) \ (b_c)$ use a fixed number of bands (respectively 28, 38 and 48) that corresponds to the energy windows given.

| Models | Excluded Wannier functions |
|--------|-----------------------------|
|        | screening channels defined corresponding with bands energy window (eV) |
| $f\text{-}ext \ (b_1)$ | $f$, Wannier weight 1-20 [-24, 27] |
| $f\text{-}ext \ (b_2)$ | $f$, Wannier weight 1-30 [-24, 47] |
| $f\text{-}ext \ (b_3)$ | $f$, Wannier weight 1-40 [-24, 57] |
| $f\text{-}ext \ (b_4)$ | $f$, Wannier weight 1-50 [-24, 67] |
| $f-(W_1) \alpha$ | [-0.8, 0.4] 1-20 [-24, 27] |
| $f-(W_1) \gamma$ | [-0.63, 0.37] 1-20 [-24, 27] |
| $fd_{t_{2g}}$-ext | $fd_{t_{2g}}$ bands 1-20 [-24, 27] |

TABLE II. Different models for the description of correlation in cerium (see text)
A. Static screening

Tab. III gives the static values of bare $v$, fully screened $W$, and cRPA value $U$ of the direct and exchange interactions as defined in Eq. (7) and (8).

1. Limiting cases: the bare and the fully screened interactions

We first focus on the bare value of the interaction as a function of the definition of the Wannier function. Here the screening is completely neglected, i.e. the dielectric matrix is set to 1 in Eq. (11). As expected, the larger the window of energy used to define Wannier functions (from the $f$ to the $f$-ext model), the larger the value of the bare interactions $U$ and $J$, ranging from 16.0 eV to 18.1 eV. Indeed, the larger the energy window, the more localized the Wannier functions.

For the fully screened interaction, the value of the interaction is much reduced by the screening. However, the same variation is logically observed as a function of the energy window used to define Wannier functions.

2. cRPA interaction

We compare now the value of the cRPA interaction for the different models. We take as a reference the bare interactions as defined in Eq. (7) and (8). For the fully screened interaction, the value of the interaction is much reduced by the screening. However, the same variation is logically observed as a function of the energy window used to define Wannier functions.

| $v$ | $f$ | 16.0 | 0.5 |
|-----|-----|------|-----|
| $v$ | $f$ | 17.1 | 0.5 |
| $v$ | $f$-ext (b) | 18.1 | 0.5 |

| $W$ | $f$ | 0.20 | 0.3 |
|-----|-----|------|-----|
| $W$ | $f$-ext (b) | 0.23 | 0.4 |

| $U_{cRPA}$ | $f$ | 3.4 | 0.4 |
|-------------|-----|-----|-----|
| $U_{cRPA}$ | $f$-ext (b) | 5.0 | 0.4 |

| $U_{cRPA}$ | $f$-ext (b) | 5.5 | 0.4 |
|-------------|-----|-----|-----|
| $U_{cRPA}$ | $f$-ext (b) | 5.7 | 0.4 |

| $U_{cRPA}$ | $f$-ext (b) | 5.7 | 0.4 |
|-------------|-----|-----|-----|
| $U_{cRPA}$ | $f$-ext (b) | 5.0 | 0.4 |

TABLE III. Bare ($v$), fully screened ($W$) and cRPA ($U_{cRPA}$) Coulomb interactions for UO$_2$. In cRPA, the screening is computed for the different models described in Tab. III. All calculations are done in the non magnetic states for LDA, and ferromagnetic states for LDA+$U$. The calculation done in the antiferromagnetic configuration is indicated by $\dagger$. Non self-consistent (nsc) calculations of $U$ use LDA+$U$ with $U$=4.5 eV and $J$=0.5 eV.
B. Dynamical screening

We discuss here the frequency dependence of the screened interaction. We plot on Fig. 3 the screened interactions as a function of the frequency.

1. Fully screened interaction.

We first discuss the frequency dependence of the fully screened interaction. For this case, only the interaction computed with the Wannier functions built in the $f$-ext (b) model is shown because the main features are mainly independent from the Wannier function construction details. Three peaks are located at 2.5 eV, 8.2 eV and 16.3 eV (called subplasmons in Ref. 35). As we will show below by comparing different models, these peaks reflect the shape of the band structure.

2. $f$ and $fp$ models

By comparing $W$ to $U$ computed in the $f$ model, one notices that the peak at 2.5 eV comes from internal transitions of the $f$ bands. It is coherent with the width of the $f$ bands which — as seen on Fig. 1 — is around 2.5 eV. Similarly, the comparison of the $U$ computed in the $fp$ model, show that the peak at 8.2 eV comes from the $p$ — $f$ transitions.

3. $f$-ext (b) model

The cRPA screened interaction as computed in the $f$-ext(b) model exhibits the three peaks also observed in the fully screened interaction $W$. Similarly to what was observed for transition metal oxides, and as discussed above, it comes from the large hybridization between oxygen and uranium, which produces a residual metallic screening in the cRPA polarizability. As a consequence the first subplasmon is observed, but its amplitude is much lower. Results for the $f$ — $fp$ (b) model are very similar to the $f$-ext(b) thus have not been reproduced here.

4. $f$-ext (b) model in LDA+$U$

In the DFT+$U$ approximation, a gap is created inside the band structure, thus the first subplasmon is suppressed. As a consequence, the variation of $U$ as a function of frequency is weaker below 4 eV. It is a justification to use a static approximation for the screened interaction.

C. Self-consistent calculation of $U$

The LDA and LDA+$U$ calculations of the cRPA lead to two different static and dynamical screened interactions. It is thus important to carry out the calculation of $U$ self-consistently. First, a LDA+$U$ calculation is performed. Then, the band structure and wavefunctions are used in a cRPA calculation to obtained a new value of $U$ on a given Wannier function. Then this value of $U$ is injected into another LDA+$U$ calculation until convergence.

Such scheme can be carried out with our present implementation but in order to guarantee the coherence of the calculation, one needs to use the same correlated basis for the calculation of the screened Coulomb interaction — Wannier functions — and the application of the Hubbard correction to the Kohn-Sham hamiltonian — atomic orbitals. As outlined in the Appendix B1 of Ref. 11, it is sufficient in our implementation to use a large number of bands to define Wannier functions, and a specific choice of the correlated occupation matrix to satisfy the former condition (Eq. B.1 of Ref. [11]).

As the calculation is computationally expensive, we have used different energy windows for the Wannier functions with increasing width. We give in Tab. III the variation of the self-consistent $U$ as a function of the energy window of the Wannier functions used in the cRPA calculation. For a large energy window, the value of $U$ and $J$ converge to $U=5.7$ eV and $J=0.4$ eV.

Our values of $U$ and $J$ are thus slightly larger than the commonly used value $U=4.5$ eV and $J=0.51$ eV. Yin et al. used a related approach to compute the screened interaction in UO$_2$. They find a value of 6 eV, only slightly larger than ours. However, there are no details about the correlated Wannier orbitals used in their calculations. The self-consistent GW approach used to compute the interaction might lead to a different band structure and thus a different screening that in our scheme. It seems however more consistent to compute...
the cRPA screened interaction with a DFT+U scheme using the cRPA interaction than a GW scheme using a fully screened interaction. The rather good agreement with our calculation might possibly comes from the fact that the actual values of the cRPA interaction and the fully screened interaction computed in DFT+U are very close because the \( f \) screening is negligible.

To conclude, in order to use the \( f \)-ext (b) model, which is the most general one, it is mandatory to carry out the calculation of the cRPA screened interaction starting from a DFT+U band structure for Mott insulators. It is especially important because most of DFT+DMFT implementations use Wannier orbitals and thus are coherent with a screened interaction computed in this model.

VI. CERIUM: RESULTS AND DISCUSSION

In this section, we present the static and dynamical cRPA screened interaction in \( \alpha \) and \( \gamma \) cerium. The third subsection is devoted to a self-consistent calculation of the static screened interaction.

A. Static screening

1. Bare interaction

Table I gives the bare interaction as computed in the \( f \)-ext (b1) model (see Tab. I). The values found for \( \alpha \) and \( \gamma \) cerium are large and in agreement to the values found by Sakuma et al.\(^{33} \). We emphasize that the Wannier functions used in this work are based on the same number of bands for \( \alpha \) and \( \gamma \) cerium. As a consequence, a slightly larger energy window is in fact used for \( \alpha \) cerium because the dispersion is more important for a compressed volume. If we use the same energy window — in the \( f \)-ext (b1) model, we find instead a value of \( V \) for the \( \gamma \) phase similar to the value found for the \( \alpha \) phase. It thus shows that the difference comes from the difference in Wannier functions. Anyway, this is a weak effect, at most 2%.

For \( \gamma \) cerium, we compute also the bare interaction in the \( f \)-ext (b2) and \( f \)-ext (b3) models with an even more extended window of energy to construct Wannier functions. We notice an increase of the bare interaction when the energy window is larger, because Wannier functions are more localized.

2. Screened interaction

We discuss now the value of \( W \) and \( U \) for a fixed volume.

As shown on Tab. I, they are both small and their small difference is only due to \( f-f \) transitions. These transitions thus contribute to a reduction of 0.3 eV of \( U \) — for both phases. In order to understand the origin of this small value of \( U \) and \( W \), we removed the transitions from all the \( f \) bands to the three bands that are just above (mainly with \( dt_{2g} \) character: see Fig. II). This is an approximated removal because bands are entangled. It corresponds to the \( fdt_{2g} \) model in Tab. II We find that removing all these screening channels increases the value of the screened interaction from 0.7 eV to 3.8 eV. So \( f-d \) transitions are a major source of screening. We note that if we had removed only the \( f \) bands — which corresponds to the \( f-W_1 \) model —, the value of \( U \) would have been small and not far from the value obtained in the \( f \)-ext (b1) model (see Tab. IV). The comparison of \( U \) computed in the \( f-W_1 \) model and the \( fdt_{2g} \) model unambiguously demonstrate the important role of the \( f-dt_{2g} \) transitions.

Nevertheless, for large volume, the appearance of \( f \) bands at the Fermi level is in disagreement with experimental photoemission spectra.\(^{59,60} \). This has been largely discussed in the literature (e.g Refs.17,20). We carried out the calculation with the LDA+U approximation with

| \text{model} | \text{Bands for Wanniers} | \text{\( \gamma \)} | \text{\( \alpha \)} |
|-----------|----------------|---|---|
| \( v \)   | \( f \)-ext (b1) | 1-20 | 23.8 | 0.7 | 24.3 | 0.7 |
| \( v \)   | \( f \)-ext (b2) | 1-30 | 25.0 | 0.7 | 25.5 | 0.7 |
| \( v \)   | \( f \)-ext (b3) | 1-40 | 24.2 | 0.7 | 24.3 | 0.7 |
| \( W \)   | \( f \)-ext (b1) | 1-20 | 0.4 | 0.5 | 0.6 | 0.5 |
| \( U_{cRPA} \) | \( f \)-ext (b1) | 1-20 | 0.7 | 0.5 | 0.9 | 0.5 |
| \( U_{cRPA} \) | \( f \)-W1 | 1-20 | 0.5 | 0.5 | 0.7 | 0.5 |
| \( U_{cRPA} \) | \( fdt_{2g} \)-ext | 1-20 | 3.8 | 0.6 | 3.8 | 0.6 |

TABLE IV. Bare (\( v \)), fully screened (\( W \)) and cRPA (\( U_{cRPA} \)) Coulomb interactions for different models for cerium in LDA and LDA+U methods. The definition of Wannier functions and screening models are defined in Tab. II In [\( f \)-ext (b\( i \))\( i=1...4 \)], the same number of bands are used to build Wannier functions in \( \alpha \) and \( \gamma \) cerium. In [\( f \)-ext (b\( i' \))\( i'=1...2 \)], two more bands are used for the calculation of \( \gamma \) cerium in order that the same energy window is used in both phases. The last 8 rows of the table gives value of \( U \) obtained from a cRPA calculation starting from a band structure obtained with the LDA+U method. \( U_{isc} \) are non self-consistently computed values of \( U \), starting from an LDA+U calculation with \( U=6 \) eV and \( J=0 \) eV. \( U_{isc} \) are values of \( U \) computed self-consistently with a given energy window to define the Wannier functions. The self-consistent calculation would be completely coherent when the energy window to define Wannier functions is large.
$U=6$ eV and $J=0$ eV. It opens a gap inside the $f$ orbitals, and pushes them apart from the Fermi level. Consequently, the screening processes associated with the $f$ orbitals lose weight and thus the value of the screened interaction is much larger. A similar effect was observed by Karlsson et al \cite{karlsson} for gadolinium. Importantly, the calculated value of $U$ depends largely on the energy window, as shown by the results ($U_{\text{nsc}}^{LDA+U}$ in Tab. IV) obtained using the $f$-ext (b$_i$)$_{i=1,2,3,4}$ models.

We also note as underlined by Sakuma et al, that 5$s$ and 5$p$ orbitals contribute much to the screening. Without their inclusion, the cRPA LDA+$U$ value for the screened interaction would be about 2 eV larger.

Nilsson et al \cite{nilsson} have computed the LDA cRPA screened interaction for $\alpha$ and $\gamma$ cerium. They compute the polarizability of the model using a disentangled band structure. Their disentanglement relies on removing the coupling between $f$ and other orbitals. As a consequence, the screening is reduced\cite{nilsson} and their value of $U$, computed from the LDA band structure, is larger than ours. The self-consistency over $U$ might however resolve the discrepancy between the two methods.

3. Screened interaction variation as a function of volume

We now compare the variation of $W$ and $U$ between the two phases. As discussed above, in subsection VIA II Wannier functions in the $f$-ext (b) model are more localized in the $\alpha$ phase because of the larger dispersion. So it should induce also an increase of 2\% for $W$ and $U$. The differences between the screened interaction in the $\alpha$ phase and in the $\gamma$ phase is however surprisingly much larger than 2\% and are respectively, of 50\% and 30\% for $W$ and $U$. As seen in Tab. III $f$ – $d$ transitions are mainly responsible for this. Indeed, the calculated value in the $f$-$d_{2g}$ model are such that $U_{\alpha} = 3.84$ eV $>$ $U_{\gamma} = 3.79$ eV. It can be understood from the evolution of the band structure as a function of the volume of cerium, as plotted in Fig. 4. When the volume increases, the $f$ and $d$ levels get closer to the Fermi level. As a consequence, the screening corresponding to the transitions from $f$ to $d$ is more effective.

The same effect holds for the LDA+$U$ approximation. Indeed the cRPA screened interaction is now larger in the $\gamma$ phase as expected: all the low energy screening channels involving $f$ levels are now weaker because they are away from the Fermi level.

B. Dynamical screening

We plot in Fig. 5 the dynamical screening computed with different models for $\alpha$ and $\gamma$ cerium. First of all, the fully screened interaction exhibits three peaks located at 3, 11 and 21 eV — for $\alpha$ cerium —, in good agreement to the results of Sakuma et al \cite{sakuma}. The peak at 21 eV comes from transition from the localized 5$p$ states as can be checked by removal of these bands from the calculation of the polarizability. Below 3 eV, both the fully screened and the cRPA interaction — as computed in LDA — are weak (below 2 eV). Above 3 eV, the Coulomb interaction becomes larger. It can be understood by looking at results from LDA+$U$ calculation. In this calculation, one $f$ band is pushed 2 eV below the Fermi level whereas the other bands are pushed 2 eV above the Fermi level\cite{karlsson}. The corresponding cRPA screened interaction does not show anymore a peak at 3 eV, because it was originating from transitions involving $f$ orbitals near the Fermi level.

We plot on Fig. 4 the evolution of the cRPA interaction as a function of frequency for different volumes. All curves have the same overall shape: a first domain (a) where the screened interaction is weak (around 2 eV) then a domain (b) where the interaction is larger (around 6 eV). The width of the domain (a) decreases with the increase of the volume. This is coherent with the argumentation outlined above in subsection VIA. The screening which creates the domain (a) is due to the proximity of $f$ and $d$ (mainly $d_{2g}$) states near the Fermi level. So this screening channel is effective only for a frequency lower than the $fd$ bandwidth. As shown in Fig. 4 as the volume increases, this bandwidth decreases in agreement with the evolution of the size of domain (a).

\caption{(Top) Band structure of fcc cerium for different volumes. The characters of $s$, $p$, $d$ and $f$ orbitals are indicated by colored fatbands. (Bottom) Screened Coulomb interaction as a function of frequency for different volumes.}
\end{figure}
C. Self-consistent calculation of $U$

As for UO$_2$, it is physically sound to carry out a self-consistent calculation of $U$ especially in the $\gamma$ phase because the LDA+$U$ spectral function is qualitatively in good agreement with the photoemission spectra. So we can expect a better description of screening.

As discussed above, the coherence of the basis for the LDA+$U$ calculation and the Wannier functions has to be preserved. We thus choose to compute the screened interaction in an atomic basis. As a consequence, a large window for the Wannier function have to be used. We thus carried out the calculation for windows with increasing widths as shown on Tab. For the $\gamma$ and $\alpha$ phases, $U$ converges at a value of 6.6 eV and 5.2 eV. The value can be trusted for the $\alpha$ phase, because this phase exhibits both a large quasiparticle peak at the Fermi level and Hubbard bands (see e.g Refs. 22).

However for the $\alpha$ phase, such description is no more valid, because the photoemission spectra exhibits both a large quasiparticle peak at the Fermi level and Hubbard bands (see e.g Refs. 22). As a consequence, neither LDA nor LDA+$U$ are able to describe the correct electronic structure. It has direct implication for the calculation of $U$: A more correct description of $U$ in $\alpha$ cerium should be carried out with a method which correctly computes the spectral function, such as DFT+DMFT. We leave it for a future study.

VII. CONCLUSION

We report an implementation of the cRPA method in the Paw based DFT/GW code ABINIT using Wannier orbitals. We show the application of the cRPA method to uranium oxide, a Mott insulator, and $\alpha$ and $\gamma$ cerium. We find that the dynamical screened interactions are particularly peaked because of interband transitions. Our main results is that an accurate calculation of $U$ for UO$_2$ and $\gamma$ cerium can only be obtained by a self-consistent procedure with a coherent choice of Wannier orbitals. We show results of the self-consistent calculation to a static $U$ using the DFT+$U$ method. For $\alpha$ cerium, we underline that a dynamical calculation of $U$ would be necessary and could be obtained by including the screening as described in DFT+DMFT.

Appendix A: Expression of $U$

This appendix gives the expression of $U$ as a function of oscillator strength $M^{n,m'}_G(q,k)$. From Eq. 1 one has the following expressions for $U$ and the oscillator matrices $M$:

$$ U_{m_1,m_2,m_3,m_4}(\omega) = \frac{1}{\Omega_{cell}} \sum_q w(q) \sum_{G,G'} M_{G,\bar{G},1}(q) \times M_{G',\bar{G},2}(q) \frac{4\pi e^{-1}}{|q + G|^2} $$

$$ M^{m,m'}_G(q,k) = \frac{1}{N_k} \sum_{k,n,n'} M^{n,n'}_G(q,k) C_{m,k}^{n,k} C_{m',k}^{n',k} $$

$C_{m,k}^{n,k}$ is the coefficient of the expansion of a Wannier function on a Kohn Sham orbital, $w(q)$ is the weight of the $q$ vector to sample the Brillouin Zone, $N_k$ is the number of $k$ vectors in the Brillouin Zone and $\Omega_{cell}$ is the cell volume. The calculation of the dielectric matrix is detailed in Refs. 52 and 53. An important point is that in the calculation of both the dielectric matrix and the screened interaction, the calculation of the oscillator matrix elements $M^{n,m'}_G(q,k)$ in the Paw formalism is required. For these two calculations, we use the scheme of Arnaud and Alouani, as implemented in ABINIT. It results from a direct application of Eq. (11) of Ref. 63 to Eq. (A2). As underlined in Ref. 52 it might require a high cutoff energy to compute the dielectric matrix, because it involves the Fourier transform of a product of the atomic wavefunctions, which are particularly localized for cerium. We converged the projector basis in

![FIG. 5. Bare, Fully screened and LDA/LDA+$U$ cRPA partially screened dynamical interactions for $\alpha$ cerium (top) and $\gamma$ cerium (bottom).](image-url)
order to obtain accurate results. This was checked in particular by the weak dependence on the sphere radius of the PAW atomic data (at most 0.1 eV).

Appendix B: Benchmark of the implementation on SrVO$_3$

This appendix gives a comparison of bare and screened interaction for SrVO$_3$ between our calculation and results obtained with the FLAPW basis by Vaugier et al and with the PAW basis by Nomura et al.

For the PAW calculations, the atomic data detailed in Ref. 39 are used.

The energy cutoffs for the wavefunction, the dielectric function and the calculation of the bare interaction are

\[15, 7\] and \[35\] Ha. We use a 6x6x6 k-mesh grid. All these parameters are sufficient to have a precision better than 0.1 eV on $U$ and $J$.

For all cRPA interactions, we find a difference of at most 0.2 eV (6%) between our calculation and results from Vaugier et al and Nomura et al. This good agreement gives a further validation of our implementation.

Appendix C: Role of the double counting correction in the cRPA calculation using a DFT+$U$ bandstructure

Whereas all results in Tab. III and IV are obtained with the FLL double counting correction, we give in this appendix results obtained with the Around Mean Field (AMF) double counting correction. This is a priori less justified than the FLL double counting correction because in our DFT+$U$ calculations electrons are not delocalized among all $f$-orbitals. For uranium dioxide (resp. 29 cerium) using the $f$-ext (b$_u$) (resp. $f$-ext (b$_j$)) model, we find $U_{\text{AMF}} = 4.5$ eV (resp. 4.2 eV) instead of 5.0 eV (resp. 5.9 eV) for the FLL double counting.

These differences can be understood from the analytical expression of the DFT+$U$ Kohn Sham potential in AMF (see e.g. Ref. 12): the Hubbard bands – and especially the minority spin bands – are lowered in energy with respect to FLL. It can thus be expected that the contribution of upper Hubbard bands to the screening processes is larger, hence the lower value of $U$.

For cerium (with only one correlated electron), the shift of Hubbard bands is -1.5 eV, and even larger for the minority bands. The value of $U$ is thus greatly reduced. Moreover, the cerium DOS hence obtained in AMF would badly compare with experimental photoemission spectra. As the FLL DOS is better, we can roughly expect that the value of $U$ obtained in FLL is better. However, and more generally, this comparison calls for a more general self-consistent scheme with a more justified double counting correction such as in the GW+DMFT scheme.

Acknowledgments

We thank Gabriel Antonius, Jordan Bieder, Silke Biermann, Matteo Giantomassi, François Jollet, Cyril Martins, Priyanka Seth and Marc Torrent for discussions about this work. We acknowledge PRACE for awarding us access to resource Marenstroem III based in Spain at BSC. This work was granted access to the HPC resources of CCRT and CINES under the allocation 201209681 made by GENCI (Grand Equipement National de Calcul Intensif).
