**Transverse shifts and time delays of spatiotemporal vortex pulses reflected and refracted at a planar interface**

Maxim Mazanov, Danica Sugic, Miguel A. Alonso, Franco Nori and Konstantin Y. Bliokh*

Abstract: Transverse (Hall-effect) and Goos–Hänchen shifts of light beams reflected/refracted at planar interfaces are important wave phenomena, which can be significantly modified and enhanced by the presence of intrinsic orbital angular momentum (OAM) in the beam. Recently, optical spatiotemporal vortex pulses (STVPs) carrying a purely transverse intrinsic OAM were predicted theoretically and generated experimentally. Here we consider the reflection and refraction of such pulses at a planar isotropic interface. We find theoretically and confirm numerically novel types of OAM-dependent transverse and longitudinal pulse shifts. Remarkably, the longitudinal shifts can be regarded as time delays, which appear, in contrast to the well-known Wigner time delay, without temporal dispersion of the reflection/refraction coefficients. Such time delays allow one to realize OAM-controlled slow (subluminal) and fast (superluminal) pulse propagation without medium dispersion. These results can have important implications in various problems involving scattering of localized vortex states carrying transverse OAM.

Keywords: beam shifts; optical angular momentum; spatiotemporal vortices; time delays.

1 Introduction

Small wavepacket shifts and time delays are currently attracting considerable attention due to their noticeable roles in nanoscience. The first example of such effects is the Goos–Hänchen shift of the beam reflected/refracted at a planar interface [1–5]. This shift is proportional to the wavevector-gradient of the logarithm of the reflection coefficient.

The temporal counterpart of this spatial shift is the Wigner time delay of a wavepacket scattered by a frequency-dependent potential [6–10]. Correspondingly, this delay is given by the frequency gradient of the logarithm of the scattering coefficient.

Another example of beam shifts is the transverse Imbert–Fedorov shift associated with the spin-Hall effect (i.e., a transverse circular-polarization-induced shift of the reflected/refracted beam) [5, 11–21]. This shift has a more complicated origin associated with the spin angular momentum carried by the wave, spin–orbit interaction, and conservation of the total angular momentum component normal to the interface.

All these shifts and time delays have been studied mostly for Gaussian-like wavepackets and beams, and all have a typical scale of the wavelength or wave period, which can be enhanced up to the beam-width or pulse-length scale using the weak-measurement technique [4, 10, 16–18, 20].

It has also been shown that the beam shifts can be modified significantly by the presence of the intrinsic orbital angular momentum (OAM) in optical vortex beams [5, 22–30]. This enhances the Gaussian-beam shifts by the factor of the OAM quantum number $\ell$ and also produces new types of shifts.

To the best of our knowledge, the role of the intrinsic OAM and vortices on time delays has not been studied...
so far. This is because optical vortex beams are usually monochromatic states unbounded in the longitudinal direction, while time delays make sense only for finite-length wavepackets.

Recently, a novel type of localized pulses carrying transverse intrinsic OAM – spatiotemporal vortex pulses (STVPs) – was described theoretically [31–34] and generated experimentally [35–40] (see also Ref. [41] for the zeroth-order Bessel STVP without OAM). Such STVPs have geometrical and OAM properties different from monochromatic vortex beams. (Note that STVPs should not be confused with principally different space-time wavepackets considered in Refs. [42–44].) Therefore, it is natural to expect that these qualitatively new objects behave differently in problems involving beam shifts and time delays.

In this work, we consider reflection and refraction of an optical STVP at a planar isotropic interface. We predict theoretically and confirm numerically a number of novel spatial shifts and time delays that are controlled theoretically and confirm numerically a number of problems involving scattering of localized vortex states with transverse intrinsic OAM – spatiotemporal vortex pulses (STVPs) – was described theoretically [31–34] and generated experimentally [35–40] (see also Ref. [41] for the zeroth-order Bessel STVP without OAM). Such STVPs have geometrical and OAM properties different from monochromatic vortex beams. (Note that STVPs should not be confused with principally different space-time wavepackets considered in Refs. [42–44].) Therefore, it is natural to expect that these qualitatively new objects behave differently in problems involving beam shifts and time delays.

In this work, we consider reflection and refraction of an optical STVP at a planar isotropic interface. We predict theoretically and confirm numerically a number of novel spatial shifts and time delays that are controlled by the value and orientation of the intrinsic OAM of the pulse. Remarkably, time delays appear in this system without any frequency dependence of the reflection/refraction coefficients, thereby allowing one to realize slow (subluminal) and fast (superluminal) pulse propagation without medium dispersion. This is in sharp contrast to Wigner time delays and is produced by the coupling of spatial and temporal degrees of freedom in spatiotemporal vortices. Our results can have important implications in various problems involving beam shifts and time delays.

In this work, we consider reflection and refraction of an optical STVP at a planar isotropic interface. We predict theoretically and confirm numerically a number of novel spatial shifts and time delays that are controlled by the value and orientation of the intrinsic OAM of the pulse. Remarkably, time delays appear in this system without any frequency dependence of the reflection/refraction coefficients, thereby allowing one to realize slow (subluminal) and fast (superluminal) pulse propagation without medium dispersion. This is in sharp contrast to Wigner time delays and is produced by the coupling of spatial and temporal degrees of freedom in spatiotemporal vortices. Our results can have important implications in various problems involving beam shifts and time delays.

Figure 1: Phase-intensity distributions of the momentum-space (left) and real-space (right) wavefunctions of the STVP (1) and (2) with \( \ell = 1, k_0 \Delta = 0.7 \) and \( y = 1.5 \). The brightness is proportional to the intensity \(|\psi|^2\), while the color indicates the phase \( \text{Arg}(\psi) \).

2 Laguerre–Gaussian STVPS

We first introduce an STVP propagating along the \( z \)-axis and carrying transverse OAM along the \( y \)-axis. For this, akin to monochromatic Laguerre–Gaussian (LG) beams [45, 46], we consider an LG-type plane-wave spectrum in the \((z, x)\) plane with the central wavevector \( k_0 = k_0 \hat{z} \) (the overbar denotes the unit vector of the corresponding axis) and zero radial quantum number (Figure 1):

\[
\tilde{\psi}(k) \propto [\gamma (k_z - k_0) + i \text{sgn}(\gamma) k_0]^{\ell} e^{-\frac{k_z^2}{2} - \frac{1}{\gamma} (x^2 + y^2)}.
\] (1)

Here, \( \ell \) is the integer vortex charge, \( \gamma \) is the factor determining the ellipticity of the STVP profile in the \((z, x)\) plane, and \( \Delta \) is the \( x \)-width of the pulse (\( \gamma \Delta \) being its \( z \)-length). Note that we do not include a distribution over \( k_y \) because for our goals it is sufficient to consider pulses unbounded along the OAM direction. If needed, an additional Gaussian distribution over \( k_y \) can provide localization along the \( y \)-axis.

The real-space form of the STVP (1) is given by the Fourier integral

\[
\psi(r, t) \propto \int \tilde{\psi}(k) e^{ikr - i\omega(t)} dk_x dk_y,
\]

where \( \omega(k) = k c \). For the purpose of this work it is sufficient to use a paraxial approximation, \( k_0 \Delta \gg 1 \), in which only linear deviations in the transverse wavevector components are considered. This leads to the following expression for a paraxial LG-type STVP where diffraction is ignored (Figure 1):

\[
\psi \propto [\gamma^{-1} \zeta + i \operatorname{sgn}(\gamma) x]^{\ell} \exp \left\{ -\frac{(\gamma^{-2} \zeta^2 + x^2)}{\Delta^2} + ik_0 \zeta \right\}.
\] (2)

where \( \zeta = z - ct \) is the pulse-accompanying coordinate. Closed-form real-space expressions that incorporate diffraction both in the paraxial and nonparaxial regimes will be described in a separate work.

For our purposes, the key features of such STVPs are: (i) their spatiotemporal vortex structure near the center: \( \psi \propto [\gamma^{-1} \zeta + i \operatorname{sgn}(\gamma) x]^{\ell} e^{ik_0 \zeta} \), and (ii) their normalized integral intrinsic OAM [33, 34]:

\[
\langle \ell \rangle = \frac{\int \text{Im} \left[ \psi^* (r \times \nabla) \psi \right] dx dy}{\int \psi^* \psi dx dy} = \frac{\gamma + \gamma^{-1}}{2} \ell \tilde{\gamma}.
\] (3)

The above equations are written for a scalar wavefunction \( \psi \). To consider polarized optical STVP, one has to multiply each plane wave in the spectrum (1) by the corresponding electric-field polarization vector \( e(k) \perp \mathbf{k} \). In the paraxial regime this does not affect the shape of the pulse and its OAM considerably, but polarization plays a crucial role in the Goos–Hänchen and spin-Hall effects [5, 17, 18].
3 Reflection/refraction of an STVP at an interface

We now consider reflection/refraction of a paraxial STVP at a planar isotropic (e.g., dielectric) interface. The geometry of the problem is shown in Figure 2. The interface is $Z = 0$, with the $Z$-axis being directed towards the second medium. The propagation direction of the incident pulse is determined by the central wavevector $k_0 = k_0(\mathbf{Z} \cos \theta + \mathbf{X} \sin \theta) \equiv k_0 \mathbf{Z}$. According to Snell’s law, the reflected and transmitted pulses have the central wavevectors $k'_0 = k_0(-\mathbf{Z} \cos \theta + \mathbf{X} \sin \theta) \equiv k_r \mathbf{Z}$ and $k'_0 = k'_0(\mathbf{Z} \cos \theta' + \mathbf{X} \sin \theta') \equiv k'_r \mathbf{Z}$ (sin $\theta' = n^{-1}$ sin $\theta$, $k'_0 = nk_0$, where $n$ is the relative refractive index of the second medium), respectively. Here, as usual in beam-shift problems, we use the accompanying coordinate frames $(x, y, z)$ and ($x', y', z'$) for the incident and reflected/transmitted pulses, Figure 2.

In contrast to the monochromatic-beam-shift problems, where the orientation of the OAM is fixed by the beam propagation direction, in our problem the transverse OAM can have different orientations with respect to the ($x, z$) plane of incidence. We will consider two basic cases shown in Figure 2:

(A) The incident STVP is localized in the ($x, z$) plane, and the intrinsic OAM $\langle \mathbf{L} \rangle$ $\parallel \mathbf{y}$.

(B) The incident STVP is localized in the ($y, z$) plane and $\langle \mathbf{L} \rangle$ $\parallel \mathbf{x}$.

To describe the main transformations of the reflected and refracted STVPs, note that the $y$-components of the wavevectors in their spectra are conserved, $k'^r_y = k_y$, while the $x$-components in the corresponding accompanying frames are related as $k'_x = -k_x$ and $k'_x = (\cos \theta / \cos \theta')k_x$.

[5] In addition, the $z$-components of the wavevectors of the transmitted pulse are $k'_z \approx nk_z$. From this, one can find that the vortex is inverted in the reflected pulse in the case (A) but not (B), and its intrinsic OAM becomes (see Figure 2):

$$\langle \mathbf{L}' \rangle_A = -\langle \mathbf{L} \rangle = -\frac{\gamma + \gamma^{-1}}{2} \mathbf{\hat{y}},$$

$$\langle \mathbf{L}' \rangle_B = \gamma + \gamma^{-1} \mathbf{\hat{y}}.$$  \hspace{1cm} (4)

Here and hereafter, the subscripts $A$ and $B$ mark the quantities related to the cases (A) and (B), respectively.

For the transmitted STVP, the above transformations of the wavevector components stretch the $x'$-width of the pulse by a factor of $\cos \theta' / \cos \theta$ and squeeze its longitudinal length by a factor of $1/n$. Therefore, the intrinsic OAM of the reflected pulses becomes

\begin{align*}
\langle \mathbf{L}' \rangle_A' &= \langle \mathbf{L}' \rangle_A - \frac{\gamma' + \gamma'^{-1}}{2} \mathbf{\hat{y}},
\gamma'_A &= \frac{\cos \theta}{n \cos \theta'} \gamma, \\
\langle \mathbf{L}' \rangle_B' &= \langle \mathbf{L}' \rangle_B - \frac{\gamma' + \gamma'^{-1}}{2} \mathbf{\hat{y}},
\gamma'_B &= \frac{\gamma}{n}. \hspace{1cm} (5)
\end{align*}

Equations (4) and (5) show that the transformations of the transverse intrinsic OAM in the case (A) is similar to those of the longitudinal OAM of monochromatic vortex beams [5, 26], only with the additional $n^{-1}$ factor in $\gamma'_A$. In turn, the case (B) differs considerably because the intrinsic OAM and vortex do not flip in the reflected pulse.

4 Transverse shifts and time delays

We are now in the position to calculate small shifts in reflected/refracted STVPs. Rigorous calculations can be
performed by applying the standard Fresnel–Snell formulas to each plane wave in the incident pulse spectrum; this is realized numerically in the next section. Here, akin to Ref. [26], we derive all the OAM-dependent shifts using general considerations.

First of all, we assume that paraxial polarized optical STVPs experience all the polarization-dependent shifts known for Gaussian wave beams or packets, i.e., angular and spatial Goos–Hänchen and spin-Hall shifts $\langle k_x^{\ell_0} \rangle_0$, $\langle x_i^{\ell_0} \rangle_0$, and $\langle y_i^{\ell_0} \rangle_0$ [5, 17, 18], where the subscript “O” indicates that the shifts are calculated for Gaussian states with $\ell = 0$. In addition to these shifts, we will determine the $\ell$-dependent shifts induced by the transverse intrinsic OAM. There are three types of such shifts.

The first type is related to the conservation of the $Z$-component of the total angular momentum in the problem and can be associated with the orbital-Hall effect of light [5, 48]. In the case (A), the intrinsic OAM has only the $y$-component, and the conservation law is satisfied trivially. In the case (B), the incident and reflected pulses have the same $Z$-components of the normalized intrinsic OAM, $\langle L_z \rangle = \langle L'_z \rangle$, Eqs. (3) and (4), while the transmitted pulse has a different OAM component: $\langle L_z \rangle \neq \langle L'_z \rangle$, Eqs. (3) and (5). Similar to the refraction of monochromatic vortex beams [5, 24, 26, 28], this imbalance between the intrinsic OAM of the incident and transmitted pulses should be compensated by the transverse $y$-shift of the refracted pulse producing an extrinsic OAM $\langle L_z \rangle^{ext} = \langle y_i \rangle \langle k'_y \rangle \simeq \langle y_i \rangle nk_0 \sin \theta'$. From here, the refracted STVP in the case (B) should undergo an additional transverse shift (see Figure 2)

$$\langle y_i \rangle_B = \frac{\langle L'_z \rangle - \langle L_z \rangle}{nk_0 \sin \theta'} = \frac{\gamma c}{2k_0} n^{-2} - 1.$$ (6)

In contrast to the analogous shift for refracted monochromatic vortex beams, the shift (6) is independent of the angle $\theta$ (apart from the small vicinity of the normal incidence $\theta = 0$, which is singular for the transverse-shift problem). The typical scale of this shift is the wavelength, although it can be enhanced by high vortex charges $\ell$ or ellipticity $\gamma \gg 1$ (narrow long pulses).

The second type of $\ell$-dependent shift is related to the angular Goos–Hänchen and spin-Hall shifts $\langle k_x \rangle_0$, see Figure 2. As has been shown for monochromatic vortex beams, in the presence of a vortex these shifts acquire an additional factor of $(1 + \gamma^2)$ [5, 26, 28], so that the additional shifts are:

$$\langle k_x^{\ell_0} \rangle_A = \gamma^2 \langle k_x^{\ell_0} \rangle_0, \quad \langle k_x^{\ell_0} \rangle_B = \gamma^2 \langle k_x^{\ell_0} \rangle_0.$$ (7)

The typical scale of these angular shifts is the inverse Rayleigh range $\sim 1/(k_0 \Delta z^2)$, and these shifts are independent of the ellipticity $\gamma$.

Finally, the third type of $\ell$-dependent shifts is related to the cross-coupling between different Cartesian degrees of freedom in a vortex. Below we use reasoning similar to that for vortex beams in Refs. [5, 26]. In the case (A), the spatiotemporal vortices in the reflected and transmitted pulses have the forms $\alpha - y^{-1}\ell + i \arg(\ell) x^\prime$ and $\alpha + y i^{-1}\ell + i \arg(\ell) x^\prime$, respectively, where $\ell x^\prime = \delta x^\prime - \Delta$ and $c$ is the speed of light in the corresponding medium. Among other polarization-dependent shifts, these pulses experience shifts in momentum space due to the angular Goos–Hänchen effect, which can be regarded as imaginary shifts in real space [5, 26, 49]: $\langle k_x^{\ell_0} \rangle_0 \rightarrow \delta x^\prime = -i \frac{\Delta}{2} \langle k_x^{\ell_0} \rangle_0$ and $\langle k_y^{\ell_0} \rangle_0 \rightarrow -\Delta x^\prime = -i \frac{\Delta}{2} \langle k_y^{\ell_0} \rangle_0$. Substituting these shifts to the vortex forms of the reflected and transmitted pulses, we find that the imaginary $x$-shifts produce real $\ell$-dependent $\ell$-shifts as follows (see Figure 2):

$$\langle \zeta^x \rangle_A = -\ell \frac{\gamma \Delta^2}{2} \langle k_x^{\ell_0} \rangle_0, \quad \langle \zeta^y \rangle_A = \ell \frac{\gamma \Delta^2}{2} \cos \theta' \langle k_y^{\ell_0} \rangle_0.$$ (8)

Applying analogous considerations to the case (B), with the reflected and transmitted vortices $\alpha - y + i^{-1}\ell + i \arg(\ell) x^\prime$ and $\alpha + y i\ell + i \arg(\ell) x^\prime$, and angular Hall-effect shifts $\langle k_x^{\ell_0} \rangle_0 \rightarrow -\delta x^\prime = -i \frac{\Delta}{2} \langle k_x^{\ell_0} \rangle_0$, where $\Delta$ is the pulse width in the $y$-direction, we obtain

$$\langle \zeta^x \rangle_B = -\ell \frac{\gamma \Delta^2}{2} \langle k_y^{\ell_0} \rangle_0, \quad \langle \zeta^y \rangle_B = \ell \frac{\gamma \Delta^2}{2} \langle k_y^{\ell_0} \rangle_0.$$ (9)

Equations (8) and (9) describe a remarkable qualitatively novel phenomenon: longitudinal shifts of STVPs reflected/refracted by a planar interface. These $\ell$-shifts are equivalent to time delays $(\delta t) = -\langle \zeta^x \rangle / c$. In contrast to the Wigner time delays, produced by the temporal dispersion (frequency dependence) of the scattered potential [6–10], here the time delays appear without any temporal dispersion. The angular Goos–Hänchen effect $\langle k_x^{\ell_0} \rangle_0$ originates from the spatial dispersion (wavevector dependence) of the Fresnel reflection/transmission coefficients, while the angular spin-Hall shift $\langle k_y^{\ell_0} \rangle_0$ is a purely geometric phenomenon which does not require any dispersion [19].

Importantly, such time delays allow one to realize slow (subluminal, $\langle \zeta \rangle < 0$) and fast (superluminal, $\langle \zeta \rangle > 0$) pulse propagation without any dispersion in optical media. Unlike previous approaches controlling slow/fast light via properties of the medium, we can control propagation time via internal spatiotemporal properties of the pulse. Note, however, that, in contrast to the wave packets in Ref. [43],
the sub- or superluminal propagation of the pulses studied here is induced by the Fresnel–Snell reflection/refraction at an interface rather than by tailoring the pulse to have a free-space group velocity differing from \( c \).

Equations (8) and (9) show that these novel OAM-dependent time delays are a rather universal phenomenon: they appear in both reflected and transmitted pulses in both cases (A) and (B). It is natural to expect that such time delays will appear in a variety of systems, both classical and quantum, involving scattering of a spatiotemporal vortex with the transverse OAM.

The typical magnitude of the longitudinal shifts (8) and (9) is the wavelength. However, angular shifts \( \langle \Delta k_y, \Delta k_z \rangle \) of the reflected pulses, and hence the corresponding new shifts (7)–(9), are enhanced resonantly for near-\( p \) polarization in the vicinity of the Brewster angle of incidence \( \theta_B = \tan^{-1}(n) \) [3, 15, 23, 50] (see Figure 4 below). This is a general phenomenon of the weak-measurement amplification of shifts for wavepackets scattered with a near-zero amplitude [10, 51, 52]. The maximum weak-measurement-amplified shift is comparable with the pulse size in the corresponding dimension, which corresponds to the amplification factor \( \sim k_0 \Delta \gg 1 \).

### 5 Numerical calculations

To verify the above theoretical derivations, we performed numerical calculations of the reflection/refraction of polarized STVPs at a dielectric interface by applying exact Fresnel–Snell’s formulas to each plane wave in the incident pulse spectrum \( \hat{E}(k) = e(k)\hat{\psi}(k) \). In the paraxial approximation, this is equivalent to applying an effective wavevector-dependent Jones matrix \( \hat{T}^{ct}(k) \) to the polarization of the central plane wave \( e_0 = e(k_0) \) [5, 17, 18], so that the reflected and transmitted pulse spectra become \( \hat{E}^{rt}(k) \approx \hat{T}^{rt}(k)e_0\hat{\psi}(k) \). After that, the spatial and angular shifts are calculated as expectation values of the corresponding position and momentum operators in the momentum representation: \( \langle y', z' \rangle = \left\langle \hat{y}' \hat{z}' \right\rangle = \left\langle \hat{E}^{rt}\left|\left(\partial \hat{y}'/\partial k_{y}'\right)\hat{E}^{rt}\right|/\left(\hat{E}^{rt}\right|^2\right\rangle, \left\langle k_{x}' k_{y}' \right\rangle = \left\langle \hat{E}^{rt}\left|k_{x}' k_{y}'\right|\hat{E}^{rt}\right\rangle/\left(\hat{E}^{rt}\right|^2\right\rangle \right\rangle \), where the inner product involves integration over the corresponding wavevector components: \( k_{x}' k_{y}' \) in the cases (A) and (B), respectively.

In doing so, it is sufficient to use an approximation that is linear in the transverse wavevector components for all shifts apart from \( \langle y' \rangle \), Eq. (6). For this shift it is necessary to consider the second-order correction from the Snell’s transformation of the wavevectors, see Eqs. (15) and (19) in Ref. [22] for a similar peculiarity in monochromatic vortex beams. In our case, this second-order correction is given by \( k_x - k_0 \approx k_x^2 - nk_0 \frac{k_y^2}{k_0} (n^2 - 1) \).
Figures 3 and 4 display results of numerical calculations of the shifts (6)–(9) for an air-glass interface with \( n = 1.5 \), generic incident STVP and different angles of incidence \( \theta \). These calculations demonstrate excellent agreement with the theoretical predictions. Furthermore, Figure 3 also shows a typical real-space intensity profile of the transmitted STVP which exhibits deformations characteristic for shifts of vortex beams [5, 29]. Figure 4 demonstrates weak-measurement enhancement [10, 51, 52], by two orders of magnitude, of the longitudinal shifts (time delays) \( \langle \zeta \rangle \) of reflected pulses for a near-\( p \) input polarization in the vicinity of the Brester angle of incidence, \( \theta \approx \theta_B \).

6 Discussion

We have described reflection and refraction of an STVP at a planar isotropic interface. The problem was considered by adopting previously developed methods for monochromatic vortex beams. In doing so, spatiotemporal vortices have a more complicated geometry with a transverse intrinsic OAM, which requires consideration of two basic cases: (A) the OAM is orthogonal to the plane of incidence and (B) the OAM lies within this plane. We have described transformations of the reflected and transmitted pulses in both of these cases. Notably, reflection in the case (A) can be used to flip the intrinsic OAM of the pulse, while refraction can be employed for changing the ellipticity of the pulse.

Most importantly, we have derived analytically and checked numerically all OAM-dependent spatial and angular shifts of the reflected and transmitted pulses in the paraxial approximation. These shifts can be divided into three types: (i) the spatial orbital-Hall-effect shift \( \langle y \rangle \) appearing for the transmitted pulse in the case (B); (ii) the OAM-amplified angular Goos–Hänchen and Hall-effect shifts \( \langle k_y \rangle \) and \( \langle k_y \rangle \); and (iii) the longitudinal shifts \( \langle \zeta \rangle \) which appear for both reflected and transmitted pulses in both cases (A) and (B). The latter is the most remarkable phenomenon, which is equivalent to time delays \( \langle \delta t \rangle = - \langle \zeta \rangle / c \) of the scattered pulses. In contrast to the well-known Wigner time delay, this effect occurs without any temporal dispersion of the scattering coefficients, from the coupling of spatial and temporal degrees of freedom in spatiotemporal vortices. Such time delays allow one to realize OAM-controlled slow (subluminal) and fast (superluminal) pulse propagation without any medium dispersion.

Due to remarkable success in experimental studies of subwavelength shifts of monochromatic optical beams and Wigner time delays of optical pulses, it is natural to expect that the new shifts and time delays predicted in this work could be measured in the near future. Furthermore, our work can stimulate a number of implications and follow-up studies. In particular, scattering of quantum spatiotemporal vortices in the geometry (A) can appear in 2D condensed-matter systems. Furthermore, we have considered only the basic case of STVP with a purely transverse intrinsic OAM and two basic geometries (A) and (B) with respect to the interface. In general, one can examine STVPs with intrinsic OAM arbitrarily oriented with respect to the propagation direction [33, 39] and interface. One can expect that in this general case, the pulse shifts could be expressed via suitably weighted sums of previously considered basic shifts. Finally, including temporal dispersion of the media and interface into consideration should add the Wigner time-delay effects, which could be coupled with spatial degrees of freedom and produce new spatial pulse shifts.
