Numerical exact diagonalization is the ultimate method of choice in order to discuss static, dynamic, and thermodynamic properties of quantum systems. In this article we consider Heisenberg spin-systems and extend the range of applicability of the exact diagonalization method by showing how the irreducible tensor operator technique can be combined with an unrestricted use of general point-group symmetries. We also present ideas how to use spin-rotational and point-group symmetries in order to obtain approximate spectra.

Keywords: Heisenberg model, Numerically exact energy spectrum

I. INTRODUCTION

The knowledge of energy spectra of small magnetic systems such as magnetic molecules is indispensable for the (complete) understanding of their spectroscopic, dynamic, and thermodynamic properties. In this respect numerical exact diagonalization of the appropriate quantum Hamiltonian is the ultimate method of choice. Nevertheless, such an attempt is very often severely restricted due to the huge dimension of the underlying Hilbert space. For a magnetic system of \( N \) spins of spin quantum number \( s \) the dimension is \( (2s+1)^N \) which grows exponentially with \( N \). Group theoretical methods can help to ease this numerical problem. A further benefit is given by the characterization of the obtained energy levels by quantum numbers and classification according to irreducible representations.

Along these lines much effort has been put into the development of an efficient numerical diagonalization technique of the Heisenberg model using irreducible tensor operators, i.e. employing the full rotational symmetry of angular momenta. A combination of this meanwhile well established technique with point-group symmetries is not very common since a rearrangement of spins due to point-group operations easily leads to complicated basis transformations between different coupling schemes. A possible compromise is to use only part of the spin-rotational symmetry (namely rotations about the \( z \)-axis) together with point-group symmetries or to expand all basis states in terms of simpler product states. To the best of our knowledge only two groups developed a procedure in which the full spin-rotational symmetry is combined with point-group symmetries. O. Waldmann combines the full spin-rotational symmetry with those point-group symmetries that are compatible with the spin coupling scheme, i.e. avoid complicated basis transforms between different coupling schemes. Sinitsyn, Bostrem, and Ovchinnikov follow a similar route for the square lattice antiferromagnet by employing \( D_4 \) point-group symmetry. This already establishes a very powerful numerical method.

In this article we show how the irreducible tensor operator technique can be combined with an unrestricted use of general point-group symmetries. The problem, that the application of point-group operations leads to states belonging to a basis characterized by a different coupling scheme whose representation in the original basis is not (easily) known, can be solved by means of graph theoretical methods that have been developed in another context. We discuss how this methods can be implemented and present results for numerical exact diagonalizations of Heisenberg spin systems of unprecedented size.

Having these methods developed we also discuss ideas of approximately obtaining energy spectra of so-called bipartite, i.e. non-frustrated, antiferromagnetic spin systems. The idea is to perform numerical diagonalizations in the orthogonal Hilbert subspaces characterized by spin and point-group quantum numbers using only a restricted but carefully chosen basis subset. We demonstrate how this idea works for archetypical spin systems such as bipartite or slightly frustrated spin rings. The advantage compared to alternative approximate methods such as Density Matrix Renormalization Group (DMRG), Lanczos, or Quantum Monte Carlo (QMC) techniques is, that one obtains many energy levels together with their spectroscopic classification which can be of great use for the discussion of Electron Paramagnetic Resonance (EPR), Nuclear Magnetic Resonance (NMR), or Inelastic Neutron Scattering (INS) spectra. In this respect our idea can provide a valuable complement to the already established approximate methods.

The article is organized as follows. In Sec. 11 we explain the idea of a combined usage of spin-rotational and point-group symmetry. Section 11 provides examples for...
full diagonalization studies. Our approximate diagonalization scheme is introduced in Sec. IV, whereas Sec. V provides example calculations on bipartite systems. The paper closes with a summary.

II. THEORETICAL METHOD

A. Irreducible tensor operator approach

The physics of many magnetic molecules can be well understood with the help of the isotropic Heisenberg model with nearest-neighbor coupling. The action of an external magnetic field is accounted for by an additional Zeeman term. The resulting Hamiltonian then looks like

$$ H = - \sum_{i,j} J_{ij} \mathbf{s}(i) \cdot \mathbf{s}(j) + g \mu_B \mathbf{S} \cdot \vec{B}. $$

The sum reflects the exchange interaction between single spins given by spin operators $\mathbf{s}$ at sites $i$ and $j$. For the sake of simplicity we assume a common isotropic $g$-tens.

Then the Zeeman term couples the total spin operator $\mathbf{S} = \sum_{i=1}^{N} \mathbf{s}(i)$ to the external magnetic field $\vec{B}$. A negative value of $J_{ij}$ refers to an antiferromagnetic coupling.

For the following discussion an antiferromagnetic nearest-neighbor exchange coupling of constant value $J < 0$ is assumed (which can easily be generalized), then the Heisenberg part can be written as

$$ H_{\text{Heisenberg}} = - J \sum_{<i,j>} \mathbf{s}(i) \cdot \mathbf{s}(j), $$

where the summation parameter $<i,j>$ indicates the summation running over nearest-neighbor spins counting each pair only once. Since the commutation relations

$$ [H_{\text{Heisenberg}}, \mathbf{S}] = 0 $$

hold it is possible to find a common eigenbasis \{|$\nu$\}\ of $H_{\text{Heisenberg}}$, $S^z$ and $S^z$. We denote the corresponding eigenvalues as $E_{\nu}$, $S_{\nu}$ and $M_{\nu}$. Due to spin-rotational symmetry, Eq. (3), the eigenvalues of the Hamiltonian can be evaluated (later) according to

$$ E_{\nu}(B) = E_{\nu} + g \mu_B B M_{\nu}, $$

where the direction of the external field $\vec{B}$ defines the $z$-axis.

Calculating the eigenvalues here corresponds to finding a matrix representation of the Hamiltonian and diagonalizing it numerically. A very efficient and elegant way of finding the matrix elements of Eq. (2) is based on the use of irreducible tensor operators. Apart from its elegance it drastically reduces the dimensionality of the problem because it becomes possible to work directly within the subspace $\mathcal{H}(S, M = S)$ of the total Hilbert space $\mathcal{H}$ characterized by quantum numbers $S$ and $M = S$; for typical dimensions compare for instance Ref. 22.

The calculation of matrix elements of the given Hamiltonian using irreducible tensor operators is compulsorily related to the application of the Wigner-Eckart-theorem. The Wigner-Eckart-theorem

$$ \langle \alpha S M | T^{(k)}_q | \alpha' S' M' \rangle = (-1)^{S-M} \langle \alpha S || T^{(k)}_q || \alpha' S' \rangle \left( \begin{array}{c} S \\ -M \end{array} \right) \left( \begin{array}{c} k \\ q \end{array} \right) \left( \begin{array}{c} S' \\ -M' \end{array} \right) $$

(5)

states that a matrix element of the $q$-th component of an irreducible tensor operator $T^{(k)}_q$ of rank $k$ is given by the reduced matrix element $\langle \alpha S || T^{(k)}_q || \alpha' S' \rangle$ and a factor containing a Wigner-3J symbol.

It should be emphasized that the reduced matrix element is completely independent of any magnetic quantum number $M$. The basis in Eq. (3) is given following the well-known vector-coupling-scheme. The quantum number $\alpha$ within the ket $|\alpha S M\rangle$ refers to a set of intermediate spin quantum numbers resulting from the coupling of single spins $s$ to the total spin quantum number $S$. In order to apply the Wigner-Eckart-theorem it is necessary to express the Heisenberg Hamiltonian in Eq. (2) with the help of irreducible tensor operators. Therefore the single-spin vector operators $\mathbf{s}(i)$ can be seen as irreducible tensor operators of rank $k = 1$ with components $q = -1, 0, 1$. The relation to the components of the vector operators is given by

$$ s^{(1)}_0 = s^z, \quad s^{(1)}_{\pm 1} = \mp \sqrt{2} (s^x \pm i s^y). $$

(6)

Writing the Heisenberg exchange term as a tensor product of the single-spin irreducible tensor operators results in

$$ H_{\text{Heisenberg}} = \sum_{<i,j>} \mathbf{S}(i) \cdot \mathbf{S}(j), $$

(7)

$T^{(0)}_q$ is a zero-rank irreducible tensor operator depending on the sets $\{k_i\}$, $l = 1, \ldots, N$, which give the ranks of single-spin irreducible tensor operators and $\{\mathbf{F}_m\}$,

$$ T^{(0)}_q = \left( \begin{array}{c} \cdots \{s^{(k_i)}_1(1) \otimes s^{(k_j)}_2(2)\}\mathbf{F}_1 \otimes s^{(k_3)}_2(3)\mathbf{F}_2 \cdots \}^{N-2} s^{(k_N)}_2(N) \right)^{(0)}. $$

(8)

The notation $T^{(0)}_q(\{k_i\}, \{\mathbf{F}_m\})|k_i = k_j = 1)$ corresponds to the situation in which the ranks of all single-spin tensor operators are zero except those at sites $i$ and $j$ which are tensor operators of rank 1.
The set \( \{ \mathcal{K}_m \} \) results from the chosen coupling scheme, for example of the form of Eq. (5), with known ranks of single-spin tensor operators taking into account addition rules for spin quantum numbers of the vector coupling scheme like \( \mathcal{K}_1 = [k_1 - k_2], \ldots, k_1 + k_2 \).

After writing the Heisenberg Hamiltonian as a sum of irreducible tensor operators the matrix elements within a basis of the form \( | \alpha S M \rangle \) can be calculated by the application of the Wigner-Eckart-theorem. The reduced matrix elements are determined using the so-called decoupling procedure. Since the irreducible tensor operator \( T^{(k)} \) is given as a tensor product of irreducible tensor operators with regard to a certain coupling scheme (comp. Eq. (8)), the reduced matrix element \( \langle \alpha S || T^{(k)} || \alpha' S' \rangle \) can successively be decomposed into a product of single-spin irreducible tensor operators and Wigner-9J symbols.

### B. General point-group symmetries

The use of irreducible tensor operators for the calculation of the matrix elements of the Hamiltonian and as a result also of the energy spectrum is essential for the treatment of magnetic molecules containing many interacting paramagnetic ions. Nevertheless, it is sometimes necessary to further reduce the dimensionality of the problem, either because computational resources are limited or a labeling of certain energy levels becomes advantageous, e.g. for spectroscopic classification. Such a reduction can be done if the Hamiltonian remains invariant under certain permutations of spin centers. Often the spin-permutational symmetry of the Hamiltonian coincides with spatial symmetries of the molecule, i.e. point-group symmetries, therefore the term point-group symmetry is used while one refers to the invariance of the Hamiltonian under permutations of spins.

Using point-group symmetries of the system results in a decomposition of the Hamilton matrix \( \langle \alpha S M || H || \alpha' S M \rangle \) into irreducible representations \( \Gamma^{(n)}(G) \) of a group \( G \) whose elements \( G(R) \), i.e. the operators corresponding to the symmetry operations \( R \), do commute with \( H \).

The symmetrized basis functions which span the irreducible representations \( n \) are found by the application of the projection operator \( \mathcal{P}^{(n)} \) to the full set of basis vectors \( | \alpha S M \rangle \) and subsequent orthonormalization. The complete set of basis vectors \( \{ | \alpha S M \Gamma^{(n)} \rangle \} \) spanning the \( n \)-th irreducible representation \( \Gamma^{(n)}(G) \) is generated by

\[
\mathcal{P}^{(n)} | \alpha S M \rangle = \frac{l_n}{h} \sum_R \chi^{(n)}(R)^* G(R) | \alpha S M \rangle ,
\]

where \( l_n \) is the dimension of the irreducible representation \( \Gamma^{(n)} \), \( h \) denotes the order of \( G \) and \( \chi^{(n)}(R) \) is the character of the \( n \)-th irreducible representation of the symmetry operation \( R \).

Equation (9) contains the main challenge while creating symmetrized basis states. The action of the operators \( G(R) \) on basis states of the form \( | \alpha S M \rangle \) has to be known. Of course, one could expand \( | \alpha S M \rangle \) into a linear combination of product states \( | m_1 m_2 \ldots m_N \rangle \). Then the action of \( G(R) \) leads to a permutation of magnetic quantum numbers \( m_i \) within the ket \( | m_1 m_2 \ldots m_N \rangle \). But, the recombination of the symmetry-transformed product states into basis states \( | \alpha S M \rangle \) will then be much too time consuming for larger systems.

Following Ref. 10 the action of \( G(R) \) on states \( | \alpha S M \rangle \) can directly be evaluated without expanding it into product states. Suppose there is a certain coupling scheme \( \alpha \) in which spin operators \( S(i) \) are coupled to yield the total spin operator \( S \). Generally the action of operators \( G(R) \) on states \( | \alpha S M \rangle \) leads to a different coupling scheme \( b \). Now those states which belong to the coupling scheme \( b \) have to be reconverted into a linear combination of states belonging to \( a \). This is technically a rather involved calculation, and one would not like to do it by hand and for every coupling scheme separately. To the best of our knowledge it has never been noted or even used that the conversion from any arbitrary (!) coupling scheme \( b \) into the desired coupling scheme \( a \) can be well automatized. Suppose there is a state \( | \alpha S M \rangle_a \) belonging to the coupling scheme \( a \). The action of a arbitrary group element \( G(R) \) results in a state \( | \alpha S M \rangle_b \) belonging to a different coupling scheme \( b \). Then the re-expression takes the following form

\[
G(R) | \alpha S M \rangle_a = \sum_{\alpha'} | \alpha' S M \rangle_a a | \alpha' S M | \alpha S M \rangle_b , \tag{10}
\]

where a term like \( a | \alpha' S M | \beta S M \rangle_b \) is known as general re-coupling coefficient. The calculation of general re-coupling coefficients and the evaluation of Eq. (10) can be performed with the help of graph theoretical methods. An implementation of these methods within a computer program is a straightforward task (follow directions given in Refs. 13,14) and one can deal with any point-group symmetry.

### III. NUMERICAL EXACT DIAGONALIZATION

In this section we like to present two applications for realistic spin systems that can be treated using irreducible tensor operator techniques and point-group symmetries, but not otherwise. Both systems – cuboctahedron and truncated tetrahedron – consist of \( N = 12 \) spins of spin quantum number \( s = 3/2 \) (Hilbert space dimension 16,777,216). The two spin systems, which are realized as antiferromagnetic molecules – cuboctahedron and truncated tetrahedron, see Fig. 1 for the structure – belong to the class of geometrically frustrated spin...
systems\cite{30,31,32} and are thus hardly accessible by means of Quantum Monte Carlo.

Figure\textsuperscript{2} shows the energy spectrum of the antiferromagnetic cuboctahedron with $s = 3/2$. This spectrum was obtained using only $D_2$ point-group symmetry which is already sufficient in order to obtain sufficiently small Hamilton matrices. In addition Fig.\textsuperscript{3} demonstrates for the subspaces of total spin $S = 0$ and $S = 1$ that a representation in the full $O_h$ group can be achieved which yields level assignments according to the irreducible representations of this group.

A complete energy spectrum allows to calculate thermodynamic properties as functions of both temperature $T$ and magnetic field $B$. For the cuboctahedron this was already done elsewhere\cite{32}. Therefore, we like to discuss another frustrated structure, the truncated tetrahedron which was synthesized quite recently\cite{29}. In principle this geometry permits two different exchange constants, one inside the triangles ($J_1$) and the other between the triangles ($J_2$), compare Fig.\textsuperscript{4}. A practical symmetry for this molecule is for instance $C_{2v}$, whereas the full symmetry is $T_d$. Figure\textsuperscript{4} displays the complete energy spectrum for the case $J_1 = J_2 = J$. The inset of Fig.\textsuperscript{4} magnifies the low-energy sector. As in the case of many other frustrated antiferromagnetic systems the spectrum exhibits more than one singlet below the first triplet\cite{30}.

\section{IV. APPROXIMATE DIAGONALIZATION}

The previous sections demonstrate that numerical exact diagonalization in connection with irreducible tensor operators is a powerful tool to investigate thermodynamical properties of large magnetic molecules. Nevertheless, sometimes the use of total-spin and point-group symme-
eigenvalues holds for the exact eigenstates of series expansion. In the case of non-degenerate eigenstates composition according to Hamiltonian \( H \) of the truncated tetrahedron with Hamiltonian and largely extend this idea. For such cases we suggest an approximate diagonalization in this section. The approximation is partially based on perturbation theory arguments. First ideas along this line were already suggested in Ref. \[33\]. We will generalize and largely extend this idea.

Let’s assume that the spin system is described by a Hamiltonian \( \hat{H} \) which acts in the Hilbert space \( \mathcal{H} \). Suppose there is a zeroth-order Hamiltonian \( H_0 \) and a decomposition according to

\[ \hat{H} = H_0 + \lambda H' \]  

(11)

In the case of non-degenerate eigenstates \( |\phi_i^{(0)}\rangle \) of \( H_0 \) the series expansion

\[ |\phi_i\rangle = |\phi_i^{(0)}\rangle + \lambda |\phi_i^{(1)}\rangle + \lambda^2 |\phi_i^{(2)}\rangle + \ldots, \]  

(12)

\[ E_i = E_i^{(0)} + \lambda E_i^{(1)} + \lambda^2 E_i^{(2)} + \ldots, \]  

(13)

holds for the exact eigenstates \( |\phi_i\rangle \) and corresponding eigenvalues \( E_i \). The index \( i = 1, \ldots, n \) denotes the states of the system. The energy eigenvalues and eigenstates in zeroth-order result from a (typically simple or even analytical) diagonalization of \( H_0 \) within an arbitrary basis of \( \mathcal{H} \).

We label the eigenvalues \( E_i^{(0)} \) and eigenstates \( |\phi_i^{(0)}\rangle \) in such a manner that

\[ E_i^{(0)} < E_{i+1}^{(0)}, \quad \forall \, i = 1, \ldots, n-1 \]  

(14)

holds. Now we do not follow conventional perturbation theory as it would lead to a successive introduction of additional terms within the expansion series in Eq. \[12\], i.e. terms with increasing order of \( \lambda \). Instead, we diagonalize the full Hamiltonian \( H \) within a reduced set \( \{ |\phi_i^{(0)}\rangle \} \), \( i = 1, \ldots, n_{\text{red}}, \) of eigenstates of \( H_0 \), where \( n_{\text{red}} \leq n \) is referred to as cut-off parameter. The resulting eigenvalues and eigenstates of this approximation are denoted as \( E_i^{\text{approx}} \) and \( |\phi_i^{\text{approx}}\rangle \). Such an approximate scheme is always converging since for \( n_{\text{red}} = n = \dim(\mathcal{H}) \) all basis states are incorporated and the diagonalization corresponds to an exact treatment of the system, i.e.

\[ E_i^{\text{approx}} \xrightarrow{n_{\text{red}} \to n} E_i, \quad |\phi_i^{\text{approx}}\rangle \xrightarrow{n_{\text{red}} \to n} |\phi_i\rangle \forall \, i. \]  

(15)

It is clear that the speed of convergence depends on the choice of \( H_0 \).

The speed of convergence will be different for the various states. Since the approximate diagonalization is performed with the \( n_{\text{red}} \) low-lying states of \( H_0 \) according to \[13\] one expects that the low-lying energy levels converge quickest against their true values. As in perturbation theory this assumption relies on the hypothesis that energetically higher-lying levels do mix into the desired low-lying state with decreasing weight. In perturbation theory this expresses itself in the second order corrections

\[ E_i^{(2)} = \sum_{i \neq j} \frac{|\langle \phi_i^{(0)} | H' | \phi_j^{(0)} \rangle|^2}{E_i^{(0)} - E_j^{(0)}}, \]  

(16)

which decrease with increasing energetic distance \( E_i^{(0)} - E_j^{(0)} \). In our approximate diagonalization the diagonal

\[ \langle \phi_i^{(0)} | H' | \phi_i^{(0)} \rangle = E_i^{(0)} + \lambda E_i^{(1)} \]  

(17)

\[ E_i^{(1)} = \langle \phi_i^{(0)} | H' | \phi_i^{(0)} \rangle \]  

(18)

and off-diagonal terms \( \langle \phi_i^{(0)} | H' | \phi_j^{(0)} \rangle \) of perturbation theory appear as diagonal and off-diagonal matrix elements of the reduced Hamilton matrix. Therefore, the approximate diagonalization includes zeroth and first order by definition and all higher orders partially up to the cut-off. The inclusion of eigenstates belonging to degenerate eigenvalues of \( H_0 \) poses no problem in our scheme. One should only include all eigenstates of a degenerate eigenvalue into the approximate diagonalization, otherwise the convergence is unnecessarily deteriorated.

### A. Approximate diagonalization based on the rotational-band model

As a zeroth-order approximation \( H_0 \) of the isotropic Heisenberg Hamiltonian \[2\] the rotational-band...
The total spin eigenstates defined as a set of eventually energetically degenerate rotational-bands. In the following a rotational-band consists of eigenvalues that form parabolas, so-called Landé rules. The spectrum of the rotational-band Hamiltonian contains the Landé numbers $S$ of the system. The eigenstates of $H$ of the sublattice spins $S_n$ to the total spin $S$ of the system. The value of $D$

$$D = 2 \cdot \frac{N_b}{N} \cdot \frac{1}{1 - 1/N_s}$$

is chosen to match the energy of the ferromagnetic state of the system described by an isotropic Heisenberg Hamiltonian. $N_s$ denotes the number of sublattices which the classical ground state of the system is composed of, $N_b$ represents the number of bonds of the system. The eigenstates of $H_{RB}$ are analytically given in the form $|S_1 \ldots S_{N_s}, S, M\rangle$, which is an enormous advantage for the following calculations. The corresponding eigenvalues are

$$E_{RB}(S_1, \ldots, S_{N_s}, S) = -\frac{DJ}{2N} \left[ S(S + 1) - \sum_{n=1}^{N_s} S_n (S_n + 1) \right].$$

The spectrum of the rotational-band Hamiltonian consists of eigenvalues that form parabolas, so-called rotational-bands. In the following a rotational-band is defined as a set of eventually energetically degenerate eigenstates $|S_1 \ldots S_{N_s}, S, M\rangle$ with fixed values of quantum numbers $S_n$ of the sublattice spins.

Figure 6 shows the spectrum of the rotational-band Hamiltonian for a spin ring of $N = 8$ spins with $s = 5/2$. The lowest bands refer to a sublattice spin configuration of $S_1 = S_2 = 4 \cdot 5/2 = 10$. The next bands result from a deviation of one sublattice spin from its maximum value $S_{n,\text{max}} = N/N_s \cdot s$. In such a way the whole spectrum can be constructed following Eq. (22). The eigenstates of the rotational-band Hamiltonian are highly degenerate due to the many possibilities of combining single spins $\mathbf{s}_i$ to the sublattice spins $S_i$ and further on sublattice spins $S_n$ to the total spin $S$.

A super-band contains those rotational-bands for which the sum of sublattices spin quantum numbers is the same. One clearly sees that within the rotational-band spectrum the low-lying super-bands are well separated.

Inserting $H_{RB}$ into Eq. (11) yields

$$H = H_{Heisenberg} = H_{RB} + H'$$

as a starting point for an approximate diagonalization. With respect to computational resources and due to the fact that the eigenstates of $H_{RB}$ are given in the form $|S_1 \ldots S_{N_s}, S, M\rangle$ the diagonalization is performed in subspaces $H(S, M = S)$ using the irreducible tensor operator technique. In addition, point-group symmetries can be used for a further reduction of the dimensionality. However, only those point-groups can be applied which do not alter the sublattice structure, i.e. do not lead to rotational-bands that are not included in the approximate basis set. Then the symmetry operations on a state belonging to a certain rotational-band will always produce states which belong to the same band.

V. BIPARTITE SYSTEMS - SPIN RING

A. Convergence

In the following we discuss the properties of the proposed approximate diagonalization for the example of an antiferromagnetic spin ring of $N = 8$ spins with $s = 5/2$. Figure 7 shows the convergence of the energy levels. In order to label the levels the full symmetry group $D_8$ of an octagon was used. One clearly sees that the convergence within the $S = 0$ subspace is fast and smooth (looking almost exponential).

In subspaces of $S = 1$ and $S = 2$ the convergence is also fast, but when only few bands are incorporated sharp steps can be observed. This is highlighted by two arrows in the bottom graph of Fig. 7. The stepwise convergence is continued in subspaces with $S > 2$ in a very regular way. It can be observed that with increasing energy within a certain subspace $H(S, M = S)$ the steps are slightly washed out. The occurrence of the steps depends on the rotational-band the states are belonging to.
FIG. 7: (Color online) Energy levels of an antiferromagnetic spin ring $N = 8$ with $s = 5/2$ as a function of the number of occupied rotational-bands used for diagonalization in subspaces $S = 0$ (top), $S = 1$ (center) and $S = 2$ (bottom). The arrows in the $S = 2$ subspace refer to the steps within the convergence behavior mentioned in the text. The states are labeled according to irreducible representations of $D_8$.

For example, the energy of the lowest state (i.e. the first rotational-band) within $H(S = 2, M = 2)$ is decreasing if 7 bands are incorporated into the approximate diagonalization while the energies of states belonging to the second rotational-band are lowered if 8 bands are incorporated, see also discussion in Sec. V B.

In Fig. 8 the convergence of some low-lying eigenstates of this spin ring are presented. The convergence behaves in analogy to the convergence of the eigenvalues. The stepwise convergence in $S = 1$ becomes obvious. Nevertheless, while using only a fraction of basis states (approximately 30% of the basis states within each subspace) the approximate low-lying eigenstates are practically converged against the exact eigenstates. In addition, it can be seen that states of higher energy converge slower than low-lying states.

We also investigate the convergence for various single spin quantum number $s$. In Fig. 9 the relative difference between the approximate energy values and the exact values is displayed for various $s$ in the subspace $S = 0$. The levels which have been chosen belong to the first three occupied rotational-bands. One clearly sees that the approximate diagonalization converges more rapidly the higher the single spin is. This is not surprising since the rotational-band model (19), which is based on classical assumptions, is itself more accurate the larger $s$ is.

B. Approximate selection rule

It turns out that the aforementioned occurrence of steps can be understood and even be employed for a further reduction of the size of Hamilton matrices. The underlying reason is that the full Hamiltonian connects states belonging to different rotational-bands with very
to the energy of the lowest state of the first rotational-band, \( E \) to the lowest state of the second rotational-band and \( E_1 \) to the lowest state of the third rotational-band respectively.

FIG. 9: (Color online) Relative difference between approximate and exact energy eigenvalues for the lowest states of the first three occupied rotational-bands for an antiferromagnetic spin ring \( N = 8 \) with various \( s \) and total spin \( S = 0 \). \( E_0 \) refers to the energy of the lowest state of the first rotational-band, \( E_1 \) to the lowest state of the second rotational-band and \( E_3 \) to the lowest state of the third rotational-band respectively.

different strength. After having inspected the reduced Hamilton matrices of various bipartite systems we arrive at the following empirical selection rule.

The matrix elements \( (S_{1,a} S_{2,a} S M|H|S_{1,b} S_{2,b} S M) \) of the full Hamiltonian between rotational-band states are (several) orders of magnitude bigger than all other matrix elements if

\[
|S_{1,a} - S_{2,a}| - |S_{1,b} - S_{2,b}| = 0 . \tag{24}
\]

Here \( S_{1,a} \) and \( S_{2,a} \) denote the total spins of sublattices one and two in \( (S_{1,a} S_{2,a} S M) \), respectively. Matrix elements that are not compatible with this rule can be neglected which (after a proper rearrangement) results in a new block-diagonal structure of the reduced Hamilton matrix. These blocks are of smaller size and can be diagonalized separately.

C. Application to \{Fe\(_{12}\}\)

We now apply the approximate diagonalization to an existing molecular spin ring\(^{39,40}\) that contains 12 Fe\(^{3+}\) ions with \( s = 5/2 \). The system can be modeled by an isotropic Heisenberg Hamiltonian with antiferromagnetic nearest-neighbor coupling \( J \).\(^{39,40}\) It was theoretically investigated in Ref.\(^{21}\) with the help of QMC methods; the exchange parameter was determined to be \( J = 35.2 \) K.

Our intention is to show that it is advantageous to combine a stochastic method such as QMC and an exact or approximate diagonalization. In such a combination the role of QMC would be to determine the exchange parameters from thermodynamical observables as done in Ref.\(^{21}\). For large systems this is practically impossible using exact or approximate diagonalization since diagonalization requires an enormous numerical effort whereas QMC methods scale much more favorable with system size for bipartite systems or even frustrated systems above a certain temperature. The role of exact or approximate diagonalization then would be to use the exchange parameters obtained by QMC for the evaluation of the energy spectrum which then can be used e.g. to

FIG. 10: (Color online) Approximate spectrum of a spin ring with \( N = 12 \) spins \( s = 5/2 \) calculated using 8 bands, \( D_2 \) point-group symmetry and the approximate selection rule in Eq.\(^{21}\) (top). Corresponding magnetization of the system (bottom). The dashed red lines refer to experimental data of the first three magnetization steps from Ref.\(^{24}\) with \( J = 35.2 \) K and \( k_B T / J = 0.01 \).

Figure \( \ref{fig:10} \) shows the low-energy part of the approximate spectrum of the \{Fe\(_{12}\}\} compound modeled by an isotropic Heisenberg Hamiltonian. For the approximate calculation of the spectrum full rotational symmetry as well as \( D_2 \) point-group symmetry are used. The calculations are performed using 8 occupied rotational-bands in the \( S = 0 \) subspace and the corresponding number of bands in subspaces with \( S > 0 \). Overall 21,570,976 states have been taken into account, which are only about 15 % of all basis states (dim(\( H \)) = 144,840,476). Additionally the approximate selection rule given in Eq.\(^{21}\) was used in order to reduce the dimensionality of the matrices which have to be diagonalized. Figure \( \ref{fig:10} \) also
displays the magnetization curve which of course can be obtained for a bipartite system by QMC as well. The magnetization steps\(^4\) can be reproduced using the approximate diagonalization.

D. Next-nearest-neighbor coupling – introducing frustration

In the previous parts we demonstrate that the approximate diagonalization scheme based on the rotational-band Hamiltonian yields good results for bipartite, i.e. unfrustrated antiferromagnetic spin systems. We now want to investigate how robust the approximate diagonalization is against the introduction of frustration. To this end we study a spin ring with \(N = 8\) and \(s = 5/2\) with antiferromagnetic nearest-neighbor coupling \(J = J_{nn}\) and an additional antiferromagnetic next-nearest-neighbor-coupling \(J_{nnn}\) which acts frustrating. In a corresponding classical system the Néel state (up-down-up-down-...) would no longer be the ground state, instead canting can occur. One can qualitatively say that with increasing \(J_{nnn}/J_{nn}\) also the frustration increases.

Figure 11 displays the effect of \(J_{nnn}\) in the subspace \(\mathcal{H}(S = 0, M = S)\) for the same system that is discussed in Fig. 7 for \(J_{nnn} = 0\). The energy gap between the ground state and the first excited state decreases with increasing frustration. Moreover, the convergence of the ground state as well as of excited states becomes slower. With \(J_{nnn}/J_{nn} = 0.4\) the convergence is rather poor and the quantum mechanical ground state now belongs to the irreducible representation \(B_1\) of the symmetry group \(D_8\). This means that the true ground state is not the result of an adiabatic continuation (\(\lambda : 0 \rightarrow 1\) in Eq. (11)) from the ground state of the rotational-band model, which belongs to \(A_1\). We just like to mention for the interested reader, that this change of the character of the ground state constitutes a so-called Quantum Phase Transition; in this case for the antiferromagnetic chain with next-nearest-neighbor exchange.

Summarizing, if frustration is only small the approximate diagonalization still yields good results. Moreover, the approximate selection rule (24) is also applicable which is very helpful in calculating the full spectrum of the system.

VI. SUMMARY

In this work we have demonstrated that the full spin-rotational symmetry can be combined with arbitrary point-group symmetries. This enables us to obtain exactly the complete energy spectrum of Heisenberg spin systems for so far unprecedented system sizes. Moreover, we have outlined a scheme to approximately diagonalize the Hamilton matrix again using the full spin-rotational symmetry and point-group symmetries. This approximation works well for bipartite antiferromagnetic spin systems. For frustrated systems the quality reduces with increasing frustration. How such a scheme can be refined for frustrated systems will be the subject of future investigations.
ACKNOWLEDGMENTS

Computing time at the Leibniz Computing Center in Garching is gratefully acknowledged as well as helpful advices of Dieter an Mey and Christian Terboven of High Performance Computing Center, RWTH Aachen, in setting up openMP directives. We also thank Boris Tsukerblat for fruitful discussions about the irreducible tensor operator technique and Nedko Ivanov for drawing our attention to some literature. This work was supported within a Ph.D. program of the State of Lower Saxony in Osnabrück.
