ABSTRACT

We report the discovery of T dwarf companions to the nearby stars HN Peg (G0V, 18.4 pc, \( \tau \sim 0.3 \) Gyr) and HD 3651 (K0V, 11.1 pc, \( \tau \sim 7 \) Gyr). During an ongoing survey of \( 5' \times 5' \) fields surrounding stars in the solar neighborhood with the Infrared Array Camera aboard the Spitzer Space Telescope, we identified these companions as candidate T dwarfs based on their mid-infrared colors. Using near-infrared spectra obtained with SpeX at the NASA Infrared Telescope Facility, we confirm the presence of methane absorption that characterizes T dwarfs and measure spectral types of T2.5 \( \pm 0.5 \) and T7.5 \( \pm 0.5 \) for HN Peg B and HD 3651 B, respectively. By comparing our Spitzer data to images from the Two-Micron All-Sky Survey obtained several years earlier, we find that the proper motions of HN Peg B and HD 3651 B are consistent with those of the primaries, confirming their companionship. HN Peg B and HD 3651 B have angular separations of 43.2 and 42.9 from their primaries, which correspond to projected physical separations of 795 and 476 AU, respectively. A comparison of their luminosities to the values predicted by theoretical evolutionary models implies masses of 0.021 \( \pm 0.009 \) and 0.051 \( \pm 0.014 \) \( M_\odot \) for HN Peg B and HD 3651 B. In addition, the models imply an effective temperature for HN Peg B that is significantly lower than the values derived for other T dwarfs at similar spectral types, which is the same behavior reported by Metchev & Hillenbrand for the young late-L dwarf HD 203030 B. Thus, the temperature of the L/T transition appears to depend on surface gravity. Meanwhile, HD 3651 B is the first substellar companion directly imaged around a star that is known to harbor a close-in planet from radial velocity surveys. The discovery of this companion supports the notion that the high eccentricities of close-in planets like the one near HD 3651 may be the result of perturbations by low-mass companions at wide separations.

Subject headings: binaries: visual — infrared: stars — stars: evolution — stars: fundamental parameters — stars: low-mass, brown dwarfs

1. INTRODUCTION

Direct imaging surveys for resolved substellar companions are vital for studies of brown dwarfs and planets. These surveys provide measurements of the frequency of companions as a function of various physical properties, such as primary mass, companion mass, separation, and age, which in turn can be used to constrain the mechanisms by which substellar companions form. In addition, compared to their isolated counterparts, each newly uncovered companion represents a superior laboratory for studying the atmospheres and evolution of substellar objects because the age, distance, and metallicity of the primary, and hence the companion, are relatively easy to measure.

A variety of criteria can be adopted for selecting primaries to search for companions. Stars for which planets have been discovered through radial velocity monitoring and young nearby stars are particularly attractive categories to consider. Several direct imaging surveys have focused on known extrasolar planetary systems (Luhman & Jayawardhana 2003, Patience et al. 2002, Mugrauer et al. 2005a, Chauvin et al. 2006), producing one companion that was initially described as a brown dwarf (Els et al. 2001) but later shown to be a white dwarf (Mugrauer & Neuhausler 2005, Lagrange et al. 2006). Similar observations have been performed toward young stars and brown dwarfs within 100 pc of the Sun (\( \tau \sim 10-400 \) Myr, Chauvin et al. 2003, Neuhausler et al. 2000a, McCarthy & Zuckerman 2004, Lowrance et al. 2005), resulting in the discovery of several substellar companions that include G196-3 B (Rehola et al. 1998), TWA 5 B (Lowrance et al. 1999, Neuhausler et al. 2000a), HR 7329 B (Lowrance et al. 2000), Guenther et al. 2001), AB Pic B (Chauvin et al. 2005a, 2005b), HD 49197 B (Metchev & Hillenbrand 2004), 2M 1207-3932 B (Chauvin et al. 2004, 2005a), and HD 203030 B (Metchev & Hillenbrand 2003). The spectral types of these companions range from late M through L but do not extend into the cooler T types.
The only known T dwarf companions to stars consist of G1 229 B (Nakajima et al. 1993; Oppenheimer et al. 1993), G1 570 D (Burgasser et al. 2001), GI 337 D (Wilson et al. 2001; Burgasser et al. 2005), ε Ind B and C (Scholz et al. 2003; McCaughrean et al. 2004), and SCR 1845 B (Biller et al. 2006), all of which orbit nearby stars that are older than ~ 1 Gyr and have no known planets.

Most resolved substellar companions have been identified through deep, high-resolution imaging at small separations (ρ ≲ 10") with adaptive optics or the Hubble Space Telescope or through shallow imaging at arbitrarily large separations with the Two-Micron All-Sky Survey (2MASS) or the Sloan Digital Sky Survey (SDSS).

OBSERVATIONS

2.1. Spitzer Mid-IR Imaging

As a part of the Guaranteed Time Observations of the IRAC instrument team, we obtained images at 3.6, 4.5, 5.8, and 8.0 μm with IRAC aboard the Spitzer Space Telescope of 73 nearby young stars (PID=34) and 48 known extrasolar planetary systems (PID=48) between late 2003 and early 2005. The plate scale and field of view of IRAC are 1"/2 and 5" × 5"/2, respectively. The camera produces images with FWHM = 1"7/6-1"9 from 3.6 to 8.0 μm (Fazio et al. 2004). The observing strategy and image reduction procedures were the same as those described by Patten et al. (2006a) for IRAC observations of M, L, and T dwarfs, except for the following modifications (Patten et al. 2006b). The data were processed using the software suite “IRACproc” developed for this program to facilitate the combining of dithered or mapped IRAC data and the rejection of cosmic-rays (Schuster et al. 2006). In order to obtain the best possible photometry of faint sources, we removed the light from each primary by fitting a scaled IRAC point spread function in each band that was derived from IRAC observations of Vega, ε Eri and ε Ind A (Marengo et al. 2003).

We measured photometry and astrometry of all point sources appearing in the reduced images of each star. We then identified candidate T dwarf companions by comparing these data to the colors of known T dwarfs (Patten et al. 2006a), which are highly distinctive from those of other astronomical sources. We did not search for M and L dwarf companions because their IRAC colors do not differ significantly from those of stars at earlier types. We also considered only candidates that had magnitudes that were consistent with the absolute magnitudes of known T dwarfs when placed at the distance of the primary. These selection criteria were applied with a statistical technique based on the k-Nearest Neighbor (k-NN; Fix & Hodge 1991), which is a nonparametric classifier appropriate when a physical model is not available or is not reliable enough for fitting the data. We adapted this data mining technique, commonly used in pattern recognition and unsupervised machine learning, to the case of astronomical photometric data. By defining an appropriate metric in the color and magnitude multi-dimensional space, we determined a “score” for each object, based on its “distance” from the colors and magnitudes of known T dwarfs. A full description of our technique is presented in Marengo & Sanchez (in preparation). The two candidates with the best scores appeared in the images of HN Peg and HD 3651. Their positions in the IRAC color-color and color-magnitude diagrams are indicated Figs. 1 and 2 and their photometric measurements are listed in Table 1. No other objects had scores that were comparable the ones for these two candidates. Followup observations of these candidates are described in the next section.

During a survey for debris disks with the Multiband Imaging Photometer for Spitzer, Bryden et al. (2006) obtained 24 μm images of HN Peg. These data encompass the candidate companion to this star that we have found with IRAC. According to analysis that was kindly performed by G. Bryden, the candidate is not detected in those 24 μm data. Extrapolating from the IRAC data with a Rayleigh-Jeans distribution, the expected 24 μm flux from the candidate is ~ 0.1 mJy while the noise in the 24 μm image is about twice this value. These relatively shallow observations were designed to detect an excess above the stellar photosphere of HN Peg rather than a faint companion.

2.2. IRTF Near-IR Imaging and Spectroscopy

We obtained near-IR spectra of the candidate T dwarf companions to HN Peg and HD 3651 with the spectrometer SpeX (Rayner et al. 2003) at the NASA Infrared Telescope Facility (IRTF) on the nights of 2006 June 15 and 30. The instrument was operated in the prism mode with a 0"/8 slit, producing a wavelength coverage of 0.8-2.5 μm and a resolution of R ~ 100. For each candidate, we obtained 20 exposures distributed between two positions along the slit. The individual exposure times were 1.5 min, resulting in a total exposure time of 30 min for each object. The slit was aligned to the parallactic angle for all observations. The spectra were reduced with the Spextool package (Cushing et al. 2004) and corrected for telluric absorption (Vacca et al. 2003).

We also used the slit-viewing camera on SpeX to mea-
ure near-IR photometry for the candidate companions on the night of 2006 July 2. The camera contained a 512 × 512 Aladdin 2 InSb array and had a plate scale of 0′′.12 pixel−1 (Ravner et al. 2003). Imaging was performed through Mauna Kea Observatory (MKO) J, H, and K filters (Simons & Tokunaga 2002; Tokunaga et al. 2002; Tokunaga & Vacca 2005). In each filter, we obtained one 30 s exposure at each of nine dithered positions. For the K-band imaging of the candidate companion to HD 3651, we performed this cycle twice. Images for a given candidate and filter were median combined to produce a flat field image, which was then divided into the original exposures. Point sources in these images exhibited FWHM = 0′′.8. We extracted photometry for each candidate companion with the task PHOT under the IRAF package APPHOT using a radius of eight pixels. These data were calibrated with images of standard stars for the MKO system (Leggett et al. 2006). The J, H, and K measurements for the two candidate companions are presented in Table 1.

3. ANALYSIS

3.1. Evidence of Binarity

When a candidate companion is identified in direct imaging of a star in the solar neighborhood, the standard method of definitively assessing its status as a binary companion consists of checking whether it shares the same proper motion as the primary. To apply this method to the two candidate T dwarfs from our IRAC images of HD 3651 and in the 2MASS Point Source Catalog. The candidate near HD 3651 is not in the 2MASS Point Source Catalog, but through visual inspection of the images, we find that it was detected in J and H.

To measure the proper motion of each candidate, we identified sources that appear in both the IRAC and the 2MASS images and measured their right ascensions and declinations in the 4.5 μm image of IRAC and in the 2MASS band in which the candidate companion has the highest signal-to-noise ratio (H for HD Peg and J for HD 3651). The differences between the IRAC and 2MASS coordinates for these objects are plotted in Figs. 3 and 4. The relatively small number of stars in each diagram is a reflection of the requirement of a detection by 2MASS: the numbers of sources detected by the IRAC images are much larger. To correct for a small offset between the coordinate systems of the IRAC and 2MASS images, we applied constant shifts to the right ascension and declination differences so that their average values were zero. In other words, we assume that the average proper motion of stars surrounding each star is zero. For comparison, we include in Figs. 3 and 4 the expected displacements of HD Peg and HD 3651 during the time interval between the 2MASS and IRAC observations (Δτ = 5.7 and 6.8 years) based on their known proper motions (Perryman et al. 1997). In each of the two diagrams, one source exhibits a motion that is significantly non-zero and that is consistent with the expected motion of the primary. These two objects are the candidate T dwarfs that we found with IRAC. Thus, these data demonstrate that both candidates have common proper motions with the primaries, which conclusively establishes their companionship. Hereafter in this paper, we refer to these new companions as HD Peg B and HD 3651 B. The positions of HD Peg B and HD 3651 B relative to their primaries are listed in Table 1.

3.2. Spectral Classification

In § 3.1.1, we identified HD Peg B and HD 3651 B as possible T dwarfs based on their mid-IR colors and magnitudes. As shown in Figs. 3 and 8, our near-IR spectra of both companions exhibit methane absorption, which is the defining spectral feature of T dwarfs (Kirkpatrick 2005). To measure the precise spectral type of each companion, we visually compared these spectra to the SpeX data for T dwarf standards that were presented by Burgasser et al. (2006a). In Figure 7, we find that the spectrum of HD Peg B agrees well with the average of the spectra of SDSS 1254-0122 (T2) and 2MASS 1209-1004 (T3). The match is clearly worse with either of these standards alone. Therefore, we assign a spectral type of T2.5±0.5 to HD Peg B.

Although the overall spectrum of HD Peg B is fit well with standard T dwarfs, the K I absorption lines at 1.25 μm appear to be weaker in HD Peg B than in the standards. In comparison, these lines become weaker with lower gravity for late-M and early-L dwarfs (McGovern et al. 2004; Kirkpatrick et al. 2000) but grow stronger with lower gravity at late-T types (Knapp et al. 2004). Based on the apparent youth of its primary (§ 3.3.1), HD Peg B should have a lower surface gravity than the standard T dwarfs in Figure 7. Thus, these data for HD Peg B seem to indicate that the gravity dependence of the K I lines is the same in early T dwarfs as it is in M and L dwarfs. However, because the spectral resolution of our data is too low for reliable measurements of these lines, a spectrum at higher resolution is needed to explore this issue definitively.

In Figure 8, we compare HD 3651 B to 2MASS 0727+1710 (T7) and 2MASS 0415-0935 (T8) and the average of the two standards. The differences between HD 3651 B and each of these three spectra are subtle, but close examination of each comparison indicates that the average of T7 and T8 provides the best match to HD 3651. For instance, the width of the continuum at 1.2-1.3 μm, the depth of the absorption at 1.6-1.8 μm, and the level of the K-band flux are all best fit by the average of T7 and T8. Therefore, we measure a spectral type of T7.5±0.5 for HD 3651 B.

3.3. Physical Properties

3.3.1. Age and Distance

Now that HD Peg B and HD 3651 B have been confirmed as companion T dwarfs, we examine their physical properties. Because these T dwarfs are companions, we can assign to them the ages and distances of their primaries, which are bright, well-studied stars in the solar neighborhood. As a result, the ages and distances of these T dwarfs, and hence the masses, radii,
and temperatures, are better constrained than those of isolated T dwarfs. We adopt the Hipparcos trigonometric distances of $18.4 \pm 0.3$ and $11.1 \pm 0.1$ pc for HN Peg A and HD 3651 A, respectively (Perryman et al. 1997). HN Peg A appears to be a young solar analog based on its activity, X-ray emission, rotation, Li abundance, and kinematics (Gaidos 1998). A comparison of the Li measurements for HN Peg A (Chen et al. 2001) to Li data for solar-type members of the Pleiades and Hyades open clusters and the Ursa Major moving group (Soderblom et al. 1990, 1993a,b) indicates that HN Peg A is probably older than the Pleiades ($\tau = 100-125$ Myr, Meyer et al. 1993; Stauffer et al. 1998) and younger than Ursa Major ($\tau = 400-600$ Myr, King et al. 2003) and the Hyades ($\tau = 575-675$ Myr, Perryman et al. 1998). A comparison of the rotational properties of HN Peg A ($P=4-5$ d, $v \sin i \sim 10$ km s$^{-1}$, e.g., Konig et al. 2006; Nordstrom et al. 2004) and these open clusters (Radick et al. 1987; Soderblom & Mavro 1993) produces the same result.

The chromospheric activity of HN Peg A suggests an age of $\sim 0.3-0.4$ Gyr (Gaidos 1998; Rocha-Pinto et al. 2004). A debris disk was recently detected around HN Peg A at 30 and 70 $\mu$m by the Spitzer Space Telescope (Bryden et al. 2006; Beichman et al. 2006), which tends to further support the youth of this star. Meanwhile, HD 3651 B is probably older than the Sun considering its fairly long rotational period ($P=48$ d, Noyes et al. 1984).

3.3.2. Luminosity

To measure the bolometric luminosities of HN Peg B and HD 3651 B, we first used the JHK photometry to flux calibrate the 0.8-2.5 $\mu$m spectrum. For each object, we constructed a spectral energy distribution that consists of these calibrated spectra, the IRAC photometry (3.2-9.2 $\mu$m), a linear interpolation of the fluxes between 2.5 $\mu$m and 3.2 $\mu$m, and a Rayleigh-Jeans distribution longward of 9.2 $\mu$m. By summing the flux in each distribution and correcting for distance, we measured $\log L/L_\odot = -4.77 \pm 0.03$ and $-5.60 \pm 0.05$ for HN Peg B and HD 3651 B, respectively.

Our luminosity measurement for HN Peg B is greater than the value produced by combining its $K$ magnitude with the bolometric corrections ($BC_K$) that have been previously measured for T2-T3 dwarfs (Golimowski et al. 2004). For instance, the bolometric luminosity for the T2 dwarf SDSS 1254-0122 from Cushing et al. (2006) implies $BC_K = 3.04$. If we combine this value of $BC_K$ with our measurement for HN Peg B and an absolute bolometric magnitude for the Sun of $M_{bol,\odot} = 4.75$, we arrive at $\log L/L_\odot = -4.83$. To explore the source of the difference in these two luminosity estimates, we compare in Figure 3 the near- and mid-IR colors of HN Peg B to those of T dwarfs compiled by Patten et al. (2006a). The 2MASS measurements from Patten et al. (2006a) have been transformed to the MKO system (Stephens & Leggett 2004). In the diagrams of colors versus spectral type in Figure 3, HN Peg B is similar to other T dwarfs near its spectral type in terms of $J-H$, $H-K$, and $K-[4.5]$, but it is redder by $\sim 0.3$ and $\sim 0.15$ mag in $K-[4.5]$ and $[4.5]-[5.8]$, respectively. The latter difference is not significant because of the large photometric errors in $[4.5]$. However, HN Peg B clearly has redder $JHK-\text{IRAC}$ colors relative to typical field dwarfs, which explains why the luminosity derived from $K$ and $BC_K$ was lower than the value measured from the photometry and spectra. In other words, if we reduced the IRAC fluxes of HN Peg B by $\sim 30\%$ so that its $JHK-\text{IRAC}$ colors were consistent with those of other T2-T3 dwarfs like SDSS 1254-0122, then our luminosity measurement would agree with the one based on $K$ and $BC_K$.

Our luminosity measurement for HD 3651 B agrees well with the value produced by combining its $K$ magnitude with $BC_K$ for T7-T8 dwarfs from Golimowski et al. (2004). In addition, the near- and mid-IR colors of HD 3651 B are consistent with those of the other T dwarfs shown in Figure 4.

3.3.3. Mass, Radius, and Temperature

We use theoretical evolutionary models to convert our luminosity and age estimates for HN Peg B and HD 3651 B to masses, effective temperatures, and radii. We perform this conversion by plotting these companions on diagrams of luminosity versus age and comparing their positions to lines of constant mass, temperature, and radius that are predicted by evolutionary models. These diagrams are presented in Figs. 10 and 11 with the models of Burrows et al. (1997) and Baraffe et al. (2003), respectively, which imply nearly identical physical properties. The models produce $M = 0.21 \pm 0.009 M_\odot$, $R = 0.108^{+0.004}_{-0.009} R_\odot$, and $T_{eff} = 1130 \pm 70$ K for HN Peg B and $M = 0.051 \pm 0.014 M_\odot$, $R = 0.082 \pm 0.006 R_\odot$, and $T_{eff} = 810 \pm 50$ K for HD 3651 B. The spectral types and physical properties of HN Peg B and HD 3651 B are summarized in Table 2.

4. DISCUSSION

We have presented the discovery of two T dwarf companions in the solar neighborhood, HN Peg B (T2.5) and HD 3651 B (T7.5). These T dwarfs are the sixth and seventh known T dwarf companions to stars and are the first T dwarfs discovered with the Spitzer Space Telescope. In this section, we describe additional notable aspects of these new brown dwarfs.

HN Peg A has been the target of high-precision radial velocity monitoring (Cummings et al. 1999; Fischer & Valenti 2002; Konig et al. 2006) and near-IR coronographic imaging (McCarthy & Zuckerman 2004), but no companions have been found through those observations. HN Peg B was bright enough to be detected by the imaging of McCarthy & Zuckerman (2004), but it was outside of their field of view ($r < 15''$). This companion was also beyond the field of view of unpublished images of HN Peg obtained with the Near-Infrared Camera and Multi-Object Spectrometer aboard the Hubble Space Telescope during General Observer program 10176. Various data from the literature indicate that HN Peg A has an age of $0.1-0.5$ Gyr ($\pm 0.3$). If the T dwarf S Ori 70 (Zapatero Osorio et al. 2002) is a field dwarf rather than a member of the young cluster $\sigma$ Ori (Burgasser et al. 2004), then HN Peg B may be the youngest known T
dwarf. HN Peg B closely resembles the recently discovered late-L companion to HD 203030 in terms of age and mass (Metchev & Hillenbrand 2005).

Several properties of HN Peg B do not behave in the manner predicted for young, low-gravity T dwarfs. Although the colors within the $JHK$ bands and within the IRAC bands are normal, all colors containing one of the former and one of the latter are redder than those of typical T dwarfs by $\sim 0.3$ mag ($\Delta J = 0.3 \pm 0.2$). In contrast, low gravity should cause these colors to become bluer, not redder, according to the theoretical spectra of Burrows et al. (2003). Based on its position in color-magnitude diagrams, HN Peg B is probably not an equal-component binary, but it could be a binary with two unequal components. Because later T dwarfs emit proportionately more flux in the mid-IR bands than at shorter wavelengths, an unresolved system of this kind (e.g., T1+T5) might be responsible for these anomalous colors. Another possible explanation is photometric variability between the dates of the IRAC and $JHK$ observations (Burgasser et al. 2002, Enoch et al. 2003).

Our estimates of the stellar parameters of HN Peg B also exhibit peculiarities. When we compare the luminosity and age of HN Peg B to the predictions of theoretical evolutionary models, we derive an effective temperature of $1130 \pm 70$ K, which is lower than the values previously measured for T dwarfs at T2-T3 ($T_{\text{eff}} \sim 1400$ K, Golimowski et al. 2003). In contrast, the spectral modeling of late T dwarfs by Burgasser et al. (2006) found that temperature should increase rather than decrease with lower gravity at a given spectral type. If this prediction is combined with the models shown in Figs. 10 and 14, then a young T dwarf should be much brighter than an older one at the same spectral type. Instead, we find that HN Peg B is at the faint end of T0-T4 dwarfs (Golimowski et al. 2004) and is at least one magnitude fainter in bolometric luminosity than expected for its assumed age. One possible explanation for these discrepancies is that the HN Peg system is much older than various data for the primary seem to indicate ($\Delta J = 3.3 \pm 1.1$). However, Metchev & Hillenbrand (2006) have recently reported the same anomalous behavior for a late-L companion near another star that appears to be young, HD 203030, and it seems unlikely that the age estimates for both stars have such large errors. Instead, the presence of this phenomenon in both HN Peg B and HD 203030 strongly indicates that the temperature of the L/T transition is dependent on surface gravity, and in a manner that has not been previously predicted.

When combined with the evolutionary models, the luminosity and age of HN Peg B translate to a mass $0.021 \pm 0.009 M_\odot$, making it one of the least massive known T dwarfs. In addition, like HD 203030 B ($M = 0.023 M_\odot$, Metchev & Hillenbrand 2006), HN Peg B is among the least massive known brown dwarf companions and is a more evolved counterpart to the widely-separated companions DH Tau B ($\tau \sim 1$ Myr, Itoh et al. 2005), CHXR 73 B ($\tau \sim 2$ Myr, Luhman et al. 2006), and AB Pic B ($\tau \sim 30$ Myr, Chauvin et al. 2005b), which have masses of $0.01-0.02 M_\odot$ (Luhman et al. 2006).

For HD 3651, radial velocity monitoring has uncovered a sub-Saturn-mass planet at 0.3 AU (Fischer et al. 2003, Fischer & Valenti 2005) while no companions have been identified in adaptive optics images (Carson et al. 2005). The latter observations did not detect HD 3651 B because their field of view was too small ($r < 15''$). Takeda et al. (2006) suggested that the high eccentricities of planets in old, single-planet systems like HD 3651 might be caused by secular perturbations from distant low-mass companions, and indeed we have found such a companion in the form of HD 3651 B. This T dwarf is the first resolved substellar companion that has been discovered in one of the extrasolar planetary systems identified in radial velocity surveys. Like HN Peg B, HD 3651 B is probably not an equal-magnitude binary brown dwarf according to its position in the color-magnitude diagram in Figure 2. HD 3651 B is a virtual twin to another T dwarf companion, Gl 570 D, in terms of spectral type, luminosity, mass, temperature, and radius (Burgasser et al. 2000, Geballe et al. 2001). As with Gl 570 D, these measurements have relatively high accuracy because of the companionship of HD 3651 B to a nearby, well-studied star, making it a valuable brown dwarf for calibrating methods of characterizing the physical properties of late T dwarfs (Burgasser et al. 2006a).

We thank Eric Majumdar for discussions regarding the ages of HN Peg and HD 3651 and Adam Burgasser for providing his spectra of T dwarf standards. We are also grateful to Geoff Bryden for checking his 24 $\mu$m images of HN Peg for a detection of the companion. K. L. was supported by grant NAG5-11627 from the NASA Long-Term Space Astrophysics program. This work is based on observations made with the Spitzer Space Telescope, which is operated by the Jet Propulsion Laboratory at the California Institute of Technology under NASA contract 1407. Support for the IRAC instrument was provided by NASA through contract 960541 issued by JPL.

ASTROMETRY AND PHOTOMETRY FOR COMpanions

| Companion   | $\rho$ (arcsec) | PA (deg) | $J$(MKO) | $H$(MKO) | $K$(MKO) | [3.6] | [4.5] | [5.8] | [8.0] |
|-------------|-----------------|----------|----------|----------|----------|-------|-------|-------|-------|
| HN Peg B    | 43.2±0.4        | 254.4±0.6| 15.86±0.03| 15.40±0.03| 15.12±0.03| 13.72±0.04| 13.39±0.02| 13.08±0.10| 12.58±0.11|
| HD 3651 B   | 42.9±0.4        | 290.1±0.6| 16.16±0.03| 16.68±0.04| 16.87±0.05| 15.38±0.04| 13.62±0.02| 14.04±0.12| 13.45±0.14|

TABLE 2
PROPERTIES OF COMpanions

| Companion   | distance$^a$ (pc) | $\rho_b$ (AU) | Spectral Type | Age (Gyr) | log $L/L_\odot$ | $M/M_\odot$ | $R/R_\odot$ | $T_{\text{eff}}$ (K) |
|-------------|-------------------|---------------|--------------|-----------|-----------------|-------------|-------------|---------------------|
| HN Peg B    | 18.4±0.3          | 795±15        | T2.5±0.5     | 0.3±0.2   | -4.77±0.03      | 0.021       | 0.009       | 1130±70             |
| HD 3651 B   | 11.1±0.1          | 476±6         | T7.5±0.5     | 7±3       | -5.60±0.05      | 0.051       | 0.014       | 810±50              |

$^a$Distance of primary (Perryman et al. 1997).
$^b$Projected physical separation from primary.
$^c$Estimated from the age, log $L/L_\odot$, and the models of Burrows et al. (1997) and Baraffe et al. (2003) in Figs. 10 and 11.

![Fig. 1.](image.png)

Fig. 1.— IRAC color-color diagrams for cool field dwarfs (open and filled circles, Patton et al. 2006a) and two candidate companions of HN Peg (lower star) and HD 3651 (upper star). The colors of these candidates are indicative of T dwarfs.
Fig. 2.— IRAC color-magnitude diagram for cool field dwarfs that have measured distances (open and filled circles and squares, Patten et al. 2006a) and two candidate companions of HN Peg (left star) and HD 13651 (right star). The absolute magnitudes of the candidates have been computed by adopting the distances of the primaries. The magnitudes and colors of these candidate companions are indicative of T dwarfs. Unlike known T dwarf binaries (Burgasser et al. 2006c, references therein), HN Peg and HD 13651 are near the lower envelope of the T dwarf sequence, indicating that they are probably not equal-component binaries.
Fig. 3.— Differences in coordinates of sources near HN Peg between an $H$-band 2MASS image obtained in 1998 and a 4.5 µm IRAC image obtained in 2004 (filled circles). The expected proper motion of HN Peg during this time interval is indicated (circle, Perryman et al. 1997). Excluding the candidate T dwarf companion from Figs. 1 and 2 (rightmost filled circle), the standard deviations of the offsets are $\sigma_{\text{RA}} = 0\farcs19$ and $\sigma_{\text{Dec}} = 0\farcs20$, which represent the errors in these measurements. The candidate T dwarf exhibits a proper motion that is non-zero at a level of 8.8 $\sigma_{\text{RA}}$ and 2.2 $\sigma_{\text{Dec}}$ and is consistent with that of HN Peg at a level of 1.8 $\sigma_{\text{RA}}$ and 1.0 $\sigma_{\text{Dec}}$, demonstrating that it is a companion.
Fig. 4.— Differences in coordinates of sources near HD 3651 between a \(J\)-band 2MASS image obtained in 1997 and a 4.5 \(\mu\)m IRAC image obtained in 2004 (filled circles). The expected proper motion of HD 3651 during this time interval is indicated (circle, Perryman et al. 1997). Excluding the candidate T dwarf companion from Figs. 1 and 2 (leftmost filled circle), the standard deviations of the offsets are \(\sigma_{RA} = 0'21\) and \(\sigma_{Dec} = 0'14\), which represent the errors in these measurements. The candidate T dwarf exhibits a proper motion that is non-zero at a level of 16 \(\sigma_{RA}\) and 18 \(\sigma_{Dec}\) and is consistent with that of HD 3651 at a level of 0.8 \(\sigma_{RA}\) and 0.1 \(\sigma_{Dec}\), demonstrating that it is a companion.

Fig. 5.— 2MASS and IRAC images of HN Peg A and B. The size of each image is 2' x 2'.

```
Fig. 6.— 2MASS and IRAC images of HD 3651 A and B. The size of each image is $2' \times 2'$.

Fig. 7.— Near-IR spectrum of HN Peg B (solid line) compared to data for the standard T dwarfs SDSS 1254-0122 (T2) and 2MASS 1209-1004 (T3) from Burgasser et al. (2006, dotted lines). The average of these standard spectra provides the best match to the spectrum of HN Peg B. The spectra have a resolution of $R = 100$ and are normalized at $1.27 \, \mu m$. 
Fig. 8.— Near-IR spectrum of HD 3651 B (solid line) compared to data for the standard T dwarfs 2MASS 0727+1710 (T7) and 2MASS 0415-0935 (T8) from Burgasser et al. (2006b, dotted lines). The average of these standard spectra provides the best match to the spectrum of HD 3651 B. The spectra have a resolution of $R = 100$ and are normalized at 1.27 $\mu$m.
FIG. 9.— Infrared colors versus spectral type for previously known T dwarfs (filled circles, [Patten et al. 2006a]) and the new T dwarf companions HN Peg B (left star) and HD 3651 B (right star).
Fig. 10.— Luminosities of HN Peg B and HD 3651 B compared to the luminosities as a function of age predicted by the theoretical evolutionary models of Burrows et al. (1997) (lines) for constant values of mass, radius, and temperature (top to bottom).
Fig. 11.—Same as Figure 10 but with the models of Baraffe et al. (2003).
