INTRODUCTION

The insulation of axons in the vertebrate nervous system by myelin is essential for efficient axonal conduction, and is thus required for the normal function of neurons. Oligodendrocytes are glial cells which myelinate axons in the central nervous system (CNS), and are generated from oligodendro-cyte progenitor cells (OPCs). In the developing spinal cord, OPCs are generated from the pMN precursor domain of the ventral spinal cord. OPCs express olig2, a basic helix-loop-helix transcription factor (Park et al., 2002b; Zhou and Anderson, 2002), and differentiate into mature oligodendro-cytes after migration into the white matter of the spinal cord. The differentiation of oligodendrocytes and the myelination of axons is a highly regulated process controlled by a number of mechanisms, including extrinsic signaling pathways and intrinsic machinery.

In the CNS, myelination disruption and re-myelination failure can cause denervating human diseases such as multiple sclerosis (MS). Primary demyelination usually occurs by a direct insult to the oligodendrocytes, and secondary demyelination occurs as a consequence of primary axonal loss (Emery, 2010). Remyelination is the process by which new myelin sheaths are restored to demyelinated axons, enabling them to recover lost function. Although the vertebrate CNS has a very limited regeneration capacity, remyelination generally occurs efficiently. However, despite the efficiency of remyelination in experimental models and in some clinical diseases, remyelination is often inadequate in
To understand the molecular mechanisms which control oligodendrocyte differentiation and myelination, the RNAs expressed by oligodendrocyte lineage cells in culture have been profiled using microarray technology (Dugas et al., 2006; Cahoy et al., 2008; Chen et al., 2009). These studies have revealed distinct classes of RNAs that are differentially expressed during oligodendrocyte differentiation and have led to the identification of new factors such as Gpr17, which encodes a G protein-coupled receptor that controls the timing of oligodendrocyte differentiation (Chen et al., 2009), and myelin gene regulatory factor (Mrf), which encodes a transcription factor necessary for expression of myelin genes (Cahoy et al., 2008). However, screening for genes differentially expressed in oligodendrocyte lineage cells using cultured oligodendrocyte lineage cells has limited potential to isolate genes responsible for oligodendrocyte differentiation and myelination because these processes are also controlled by extracellular ligands and molecules secreted from neurons, such as Jagged, PSA-NCAM, and LINGO-1 (Wang et al., 1998; Charles et al., 2000; Mi et al., 2005). Here, a microarray screening method was used to isolate genes involved in oligodendrocyte differentiation using oligodendrocyte lineage cells sorted from transgenic zebrafish. Oligodendrocyte lineage cells expressing enhanced green fluorescent protein (EGFP) were isolated by fluorescence activated cell sorting (FACS), and the gene expression profiles of undifferentiated OPCs and differentiated oligodendrocytes were compared. Seven genes not previously known to be involved in oligodendrocyte differentiation were identified, and their expression during oligodendrocyte development was validated.

MATERIALS AND METHODS

Animals

Zebrafish embryos used in this study were wild-type AB line, Tg (olig2:egfp) (Shin et al., 2003), Tg(sox10:egfp) (Carney et al., 2006) and raised at 28.5°C in egg water or embryo medium (15 mM NaCl, 0.5 mM KCl, 1 mM CaCl₂, 1 mM MgSO₄, 0.15 mM KH₂PO₄, 0.05 mM NH₄PO₄, 0.7 mM NaHCO₃, EM). Embryos were staged according to days post fertilization (dpf) and morphological criteria (Kimmel et al., 1995).

Trichostatin A treatment

Embryos were dechorionated and incubated in EM with histone-deacetylase inhibitor Trichostatin A (Tsai et al., 2006) at a concentration of 100 ng/ml.

Cell dissociation for flow cytometry

Embryos were raised until appropriate stage and anesthetized with ethyl 3-aminobenzoate methane-sulfonic acid on ice. A thousand embryos were chopped into several pieces and transferred into 1.5 ml eppendorf tube. Collected samples were rinsed with calcium-, magnesium-free Ringers solution for 20 min, then washed with Dulbecco’s phosphate buffered saline (D-PBS) (GIBCO) three times. Tissue was digested with 100 µl of D-PBS containing 35 µl of Liberace Blendzyme 3, followed by incubation at 29°C for 15 min with occasional mixing. After incubation, 1 ml of trypsin (GIBCO) was added and incubated at 29°C for 15 min until complete dissociation. To inactivate trypsin, we added 2 ml of D-PBS containing 10% fetal bovine serum (FBS) and filtered the solution through a cell strainer (BD Falcon) to remove undissociated cell clusters. We collected dissociated cells by centrifugation at 300 g at 4°C for 5 min and rinsed twice with D-PBS containing 10% FBS. Dissociated cells were collected by centrifugation and resuspended in PBS containing 1 mM EDTA, 25 mM HEPES (pH 7.0) and 1% FBS. Cell suspensions were separated into GFP+ and GFP- cells by BD FACSAria II (Becton Dickinson) performed at room temperature under sterile conditions. Isolated GFP+ and GFP- cells were collected in D-PBS/10% FBS pre-coated tubes with RNase inhibitor.

RNA extraction

Isolated cells were collected by low-speed centrifugation and homogenized in TRIzol solution (Invitrogen) subsequently. Total RNA extraction was performed as described previously (Peterson and Freeman, 2009). Isolated total RNA was cleaned up with RNeasy midi kit (Quigen) and qualified as a microarray target samples using Bioanalyzer 2100 system (Agilent) and NanoDrop spectrophotometer.

Hybridization of agilent gene chips

1 µg of qualified total RNA was amplified and labeled with Cy3, Cy5 dyes. Hybridization was performed with Zebrafish Agilent Gene Expression Microarray Chips (Agilent), followed by washing step. Hybridized chips were then scanned, nor-malized and analyzed.

Semi-quantitative and quantitative RT-PCR

cDNA was synthesized using ImProm-II reverse transcription system (Promega). The quantitative real-time PCR was performed using the Lightcycler system (Roche Applied Science) with
Identification of EGFP expression in oligodendrocyte lineage cells of transgenic zebrafish

To identify the genes involved in oligodendrocyte differentiation and myelination, we isolated OPCs and differentiated oligodendrocytes expressing EGFP from the transgenic zebrafish and compared their transcriptional profiles. Therefore, the embryo stages suitable for collecting OPCs and differentiated oligodendrocytes were first identified. Previously, we have shown that *olig2* expressing precursor cells in the pMN precursor domain of the ventral spinal cord first generate motor neurons during neuro-gensis and later produce migrating OPCs, which express *olig2* continuously to the mature oligodendrocyte stage (Park et al., 2002a; Park and Appel, 2003; Park et al., 2004). As soon as OPCs are specified in the pMN precursor domain, *sox10* starts to be expressed specifically in the oligodendrocyte lineage cells. Larvae carrying the *Tg(olig2:egfp)* and *Tg(sox10:egfp)* transgenic reporters, which express EGFP under the control of the *olig2* and *sox10* promoters (Shin et al., 2003; Carney et al., 2006), respectively, were examined for use in the transcriptome analysis.

Expression of EGFP in OPCs and mature oligodendrocytes at several developmental stages in the *Tg(olig2:egfp)* and *Tg(sox10:egfp)* larvae was verified by fluorescence microscopy using transverse sections of the spinal cord. By 2 days post-fertilization (dpf), *sox10:EGFP* cells are located in the gray matter of the spinal cord, in which Hu+ neurons are located, indicating that *sox10:EGFP* cells are undifferentiated OPCs (Fig. 1A, arrow-heads). By 5 dpf, *sox10:EGFP* OPCs have migrated to the white matter of the spinal cord and differentiated into mature oligodendrocytes with multiple processes (Fig. 1B, arrows). Labeling of the spinal cord of *Tg(olig2:egfp)* larvae with anti-Sox10, a marker for OPCs and mature oligodendrocytes, revealed that Sox10+, *olig2:EGFP* cells are located in the gray matter of ventral spinal cord at 2 dpf, indicating that these cells are undifferentiated OPCs (Fig. 1C,

**RESULTS AND DISCUSSION**

*Identification of EGFP expression in the oligo-dendrocyte lineage cells of transgenic zebrafish*

Embryos were anesthetized until movement had ceased and fixed in 4% paraformaldehyde over-night. Fixed embryos were embedded in 1.5% agar with 5% sucrose blocks and equilibrated by 30% sucrose solution. Frozen blocks were sliced into 10 µm sections on glass slides using cryostat micro-tome. Sections were rinsed with PBS several times and then blocked in 2% bovine serum albumin with sheep serum. Embryos were processed for immunohistochemistry, following primary antibodies were used: rabbit anti-Sox10 (1 : 250), rabbit anti-MBP (1 : 100), rabbit anti-GFP (1 : 500, Abcam) and mouse anti-HuC/D (16A11 : 0.1, Molecular Probes, Eugene, OR). For fluorescent detection of antibody labeling, we used Alexa Fluor 568-conjugated goat anti-mouse IgG, Alexa Fluor 568-conjugated goat anti-rabbit IgG, and Alexa Fluor 488-conjugated goat anti-rabbit IgG (1 : 500, Molecular Probes). Photos were taken using a confocal lasers scanning microscope (LSM 510 Pascal, Carl Zeiss).

**Fig. 1.** Identification of EGFP expression in oligodendrocyte lineage cells in transgenic zebrafish lines. All panels show transverse sections of the spinal cord, dorsal side at the top of the image. (A, B) Labeling of *Tg(sox10:egfp)* larvae with anti-Hu at 2 dpf (A) and 5 dpf (B). Arrowheads indicate OPCs in the gray matter and arrows indicate differentiated oligodendrocytes in the white matter of the spinal cord. (C, D) Labeling of *Tg(olig2:egfp)* larvae with anti-Sox10 at 2 dpf (C) and 5 dpf (D). Arrowheads indicate *olig2:EGFP*, Sox10+ OPCs in the gray matter and arrows indicate *olig2:EGFP*, Sox10+ differentiated oligodendrocytes in the white matter of the spinal cord. (E, F) Labeling of TSA-treated (E) and untreated (F) *Tg(olig2:egfp)* larvae with anti-Sox10 at 5 dpf. Arrows indicate *olig2:EGFP*, Sox10+ differentiated oligodendrocytes in the white matter of the spinal cord.
arrowheads). Sox10⁺, olig2:EGFP⁺ cells migrated to the white matter and differentiated into mature oligodendrocytes possessing multiple process by 5 dpf (Fig. 1D, arrows). These data demonstrated that in the spinal cord of Tg(olig2:egfp) and Tg(sox10:egfp) larvae, EGFP-expressing cells are OPCs at 2 dpf and mature oligodendrocytes at 5 dpf. Thus, OPCs and mature oligodendrocytes can be obtained by sorting EGFP⁺ cells from Tg(olig2:egfp) and Tg(sox10:egfp) 2 dpf and 5 dpf larvae, respectively.

To identify the genes specific to oligodendrocytes, a comparison of transcriptional profiles of normal and oligodendrocyte-deficient larvae could be conducted. Previously, oligodendrocyte development was shown to require histone deacetylase (HDAC) activity (Marin-Husstege et al., 2002; Cunliffe and Casaccia-Bonnefil, 2006; Ye et al., 2009), and treatment with the HDAC inhibitor Trichostatin A can block formation of oligodendrocytes in zebrafish (Tsai et al., 2006). Consistent with previous reports, we found that treatment of Tg(olig2:egfp) embryos with TSA from 36 hours post fertilization (hpf) to 5 dpf blocked migration of Sox10⁺, olig2:EGFP⁺ oligodendrocytes, which are located in the white matter of the spinal cord in the normal 3 dpf larvae (Fig. 1E and F, arrows indicate mature oligodendrocytes). These data indicated that comparison of transcriptional profiles of EGFP⁺ cells from TSA-treated and untreated Tg(olig2:egfp) larvae can be used to identify genes expressed specifically in oligodendrocytes.

Microarray-based transcriptome analysis to identify genes involved in oligodendrocyte differentiation

On the basis of the above data, OPCs and mature oligodendrocytes were purified from the dissociated cells of Tg(olig2:egfp) and Tg(sox10:egfp) larvae at 2 dpf and 5 dpf, respectively, using FACS. EGFP⁺ cells were also purified from TSA-treated and untreated 3 dpf Tg(olig2:egfp) larvae. Prior to sorting of EGFP⁺ cells, dissociated cells from the Tg(olig2:egfp) and Tg(sox10:egfp) larvae contained 20% EGFP⁺ cells (Fig. 2A–C). After sorting, an average of 98% of the sorted cells was EGFP⁺ OPCs or mature oligodendrocytes (Fig. 2D–F). To confirm the purity of the sorted cells, total RNA was isolated from EGFP⁺ mature oligodendrocytes and semi-quantitative RT-PCR was performed with several PCR primers specific to mature oligodendrocytes, neurons, and blood vessels. Mature oligodendrocyte specific genes were successfully amplified by RT-PCR, but neuron and blood vessel specific genes were not. These data indicate that oligodendrocyte lineage cells were specifically isolated by FACS (Fig. 2G).

To compare the transcriptional profiles of OPCs and mature oligodendrocytes, we purified RNA from the sorted cells and synthesized dye-labeled cDNAs, which were hybridized to microarray gene chips. A total of 19,956 transcripts were examined with the Agilent zebrafish gene expression microarray. Genes up-regulated by 2.5-fold in mature oligodendrocytes were identified as genes required for oligodendrocyte maturation and genes down-regulated by 2.5-fold in mature oligodendrocytes were identified as genes for oligodendrocyte maturation and genes down-

Fig. 2. Sorting of EGFP⁺ oligodendrocytes from transgenic zebrafish using FACS. Differential interference contrast images (DIC; A, D), fluorescence images (B, E), and combined DIC and fluorescence images of the same samples (C, F). (A–C) Tg(sox10:egfp) larvae were trypsinized to dissociate them into single cells at 5 dpf. (D–F) EGFP⁺ oligodendrocytes were sorted from Tg(sox10:egfp) larvae by FACS. More than 98% of the sorted cells were EGFP⁺ oligodendrocytes. (G) Semi-quantitative RT-PCR with RNA purified from the sorted 3 dpf sox10:EGFP⁺ cells and PCR primers specific to genes expressed in mature oligodendrocytes (sox10, mbp, gfp), neurons (Hu), and blood vessels (flk). β-actin was used as a loading control.

Fig. 3. Comparison of the transcriptional profiles obtained from three different algorithms. (A, B) Venn diagrams show the numbers of genes detected by three different algorithms, including the numbers of overlapping genes. (A, B) The intersection of the three databases contains 32 genes that were up-regulated in differentiated oligodendrocytes (A) and 19 genes that were down-regulated in differentiated oligodendrocytes (B). (C) Microarray profiles were validated by examining the expression profiles of genes known to be specifically expressed in differentiated oligodendrocytes, including mpzs, plp1b, mag, cldnk1, and flj13639.
regulated to 0.3-fold or less in mature oligodendrocytes were identified as genes required for the maintenance of OPC status. In addition, a total of 32 up-regulated and 19 down-regulated genes were selected from the intersection of the three algorithms (Fig. 3A, B). To confirm the accuracy of the microarray screen, we searched the expression profile of well-characterized genes required for the oligodendrocyte differentiation, such as mpz, plp1b, mag, cldnk and flj13639, and found that the expression levels of these genes were highly elevated in mature oligodendrocytes (Fig. 3C), indicating that our microarray analysis was successful.

Validation of microarray data by quantitative RT-PCR (qRT-PCR)

To validate the microarray data, we performed a qRT-PCR analysis of selected genes which exhibited highly elevated expression levels in the differentiated oligodendrocytes. We selected seven genes not previously known to be involved in oligodendrocyte differentiation. The expression levels for bhlhe40 (basic helix-loop-helix family, member e40, NM_212679), dlg1 (discs, large (Drosophila) homolog 1, NM_199526), rbp2a (retinol binding protein 2a, cellular, NM_153004), rock2b (rho-associated, coiled-coil containing protein kinase 2b, NM_001093747), sepp1a (selenoprotein P, plasma, 1a, NM_178297), zgc:110190 (NM_001020570) and zgc:112160 (NM_001017724) were evaluated by qRT-PCR using RNA purified from the sorted OPCs and mature oligodendrocytes. Myelin basic protein (mbp) was used as a positive control, and the expression levels of the selected genes are presented as the relative induction in differentiated oligodendrocytes compared to OPCs. Consistent with the microarray profiles, qRT-PCR demonstrated that the expression of these seven genes was highly elevated in differentiated oligodendrocytes (Fig. 4), suggesting that all seven genes may be involved in oligodendrocyte differentiation.

Basic helix-loop-helix family member e40 (bHLHB2, also known as Dec1/Eip1/Sharp2/Stra13/Clast5) is a novel cAMP-inducible bHLH protein family member. Stra13 is required for the proliferation and differentiation of nerve cells. Stra13 controls growth arrest, and represses the expression of cell proliferation-associated genes through an HDAC1-independent mechanism (Sun and Taneja, 2000). Dec1 is expressed in the nuclei of endothelial, glial and neuronal cells in brain tissue (Preussner et al., 2005). Since the bHLHB2 expression level is elevated in differentiated oligodendrocytes, we hypothesize that bHLHB2 plays a role in oligodendrocyte differentiation by regulating the OPC cell cycle. Discs-large homolog 1 (Dlg1) is a multi-domain scaffolding protein that is involved in protein trafficking in polarized cells and membrane addition in Drosophila (Lee et al., 2003; Gorczyca et al., 2007). Dlg1 is expressed in myelin-forming Schwann cells, and enriched in Schwann cell paranodes where myelin outfoldings preferentially arise. In-terestingly, dgl1 interacts with kinesin 13B (kif13B) and Sec8, which play a central role in oligodendrocyte membrane formation by regulating the re-cruitment of vesicles that transport myelin proteins, suggesting that dgl1 function may be required for oligodendrocyte differentiation (Bolis et al., 2009). Retinol binding protein 2a (Rbp2a/CRBP) is a cytoplasmic retinol-specific binding protein and is expressed in the lateral ganglionic eminences (LGE), where a second wave of OPCs originate in the telencephalon (Kessaris et al., 2008). Retinol is naturally converted into retinoic acid which regulates the timing of oligodendrocyte differentiation in vivo (Barres et al., 1994). Therefore, we hypothesize that Rbp2a may play a role in oligodendrocyte development together with retinol.

Rho-GTPase family proteins play important roles in coordinating
the remodeling of the actin cyto-skeleton during myelination. A key effector of Rho-GTPase is Rho-kinase (ROCK), a serine/threonine kinase that regulates cell migration, proliferation and survival (Mueller et al., 2005). ROCK is expressed in Schwann cells at the onset of myelination, and pharmacological inhibition of ROCK activity causes Schwann cells form aberrant short myelin segments. However, after ROCK inhibition is removed, new myelin segments are formed normally (Melendez-Vasquez et al., 2004), indicating that ROCK plays an important role together with Rho-GTPase in the progression of the Schwann cell membrane encasement of the axon during myelination. Rho-associated coiled-coil containing protein kinase 2b (Rock2b) is a ROCK family protein and our microarray data showed that Rock2b expression was highly elevated in myelinating oligodendrocytes, suggesting the possibility that Rock2b function is involved in myelin formation in CNS oligodendrocytes. Selenium is required for normal up-regulation of myelin genes in differentiating oligodendrocytes. Therefore, two novel factors are expressed at elevated levels in differentiated oligodendrocytes. We also examined the previously unannotated genes zgc:110191 and zgc:112160. These two novel factors are expressed at elevated levels in differentiated oligodendrocytes.
