(Dated: July 2005)

The electronic structure of radially polarized excitons in structured nanorings is analyzed, with emphasis in the ground-state properties and their dependence under applied magnetic fields perpendicular to the ring plane. The electron-hole Coulomb attraction has been treated rigorously, through numerical diagonalization of the full exciton Hamiltonian in the non-interacting electron-hole pairs basis. Depending on the relative weight of the kinetic energy and Coulomb contributions, the ground-state of polarized excitons has “extended” or “localized” features. In the first case, corresponding to small rings dominated by the kinetic energy, the ground-state shows Aharonov-Bohm (AB) oscillations due to the individual orbits of the building particles of the exciton. In the localized regime, corresponding to large rings dominated by the Coulomb interaction, the only remaining AB oscillations are due to the magnetic flux trapped between the electron and hole orbits. This dependence of the exciton, a neutral excitation, on the flux difference confirms this feature as a signature of Coulomb dominated polarized excitons. Analytical approximations are provided in both regimens, which accurate reproduce the numerical results.

I. INTRODUCTION

Nanoscale semiconductor structures have been the subject of numerous theoretical and experimental investigations in the last few years. The effects of quantum confinement in these nanosystems strongly modify their electronic and optical properties, offering exciting possibilities for technological applications. Among these, a particular class of structures with annular geometry called nanorings are being intensively investigated after the experimental observation of the AB effect in small metallic rings. With the strong development in the nanofabrication, it is now possible the formation of different types of semiconductor nanorings. This gives us the exciting opportunity to observe new quantum interference phenomena in magneto-optical experiments. Several theoretical papers have reported studies about the influence of the different geometric-confinement parameters and the presence of impurities on the spectrum in a semiconductor quantum ring in magnetic field. The effects of an external electric field on the AB oscillations in the energy spectrum of quantum rings have been also reported. Most of the experimental work has been performed on charged excitons in nanorings and in neutral excitons in type-II quantum dots. The possibility of the observation of the so-called “optical” AB has been an interesting and controversial subject in the recent years. It was predicted that the polarization of a neutral exciton in a quantum ring can originate a magnetic interference effect such that the ground-state of the exciton alternates between states with zero (bright) and nonzero (dark) angular momentum for increasing magnetic field. The finite polarization of the exciton can be obtained by asymmetries in the confinement potentials of the electron and holes or by means of a uniform electric field applied in the ring plane. In the present paper we report a study of the effects of the Coulomb interaction on the electronic structure of excitons in nanorings. We consider radially polarized excitons and we make a detailed analysis of the ground-state properties and its dependence with magnetic fields applied perpendicular to the ring plane. We include rigorously the electron-hole Coulomb interaction and discuss different regimes of excitonic confinement. We also provided analytical approximations which are useful for semi-quantitative estimations in well-defined regimens.

II. THE MODEL AND METHOD OF SOLUTION

The effective-mass excitonic Hamiltonian in a quantum-ring structure subject to an external magnetic field parallel to the ring axis, which we take to be the z axis, can be simplified under some suppositions. In the first place, the electron and hole coordinates along the z-axis can be simplified under some suppositions. In the first place, the electron and hole coordinates along the z-direction may be “frozen” at the same in-plane value (say, $z_e = z_h = 0$). This is consistent with the fact that for all the semiconductor quantum rings produced by today’s semiconductor growth techniques, the confinement along the z-direction (usually given by a compositional
barrier) is much stronger that the in-plane confinement. This gives rise to a strong quantization along $z$. In the second place, the radial displacements of the electron and hole may also be “frozen” at different radial coordinates, $R_e$ and $R_h$, respectively. This is done by assuming that the effective self-consistent potentials, for electron and for hole, have different radial positions for their respective minima and by realizing that the quantization in the radial direction is usually stronger than in the azimuthal direction, for both of them. These two approximations leads directly to:

$$\hat{H}_{\text{exc}}(\theta_e, \theta_h) = \hat{H}_{\text{exc}}^0(\theta_e, \theta_h) + U_e(\Delta \theta), \quad (1)$$

where

$$\hat{H}_{\text{exc}}^0(\theta_e, \theta_h) = \frac{\hbar^2}{2m_e R_e^2} \left( -i \frac{\partial}{\partial \theta_e} + \phi_e \right)^2 + \frac{\hbar^2}{2m_h R_h^2} \left( i \frac{\partial}{\partial \theta_h} + \phi_h \right)^2, \quad (2)$$

is the sum of the electron and hole kinetic energies, and the Coulomb interaction is given by

$$U_e(\Delta \theta) = -\frac{e^2}{\varepsilon (R_e^2 + R_h^2)^{1/2}} \frac{1}{\left[ 1 - r \cos(\Delta \theta) \right]^{1/2}}. \quad (3)$$

In the above equations $\Delta \theta = \theta_e - \theta_h$, $m_e$ and $m_h$ are the electron and hole effective masses, $(R_e, \theta_e)$ and $(R_h, \theta_h)$ are the radial and angular electron and hole polar coordinates, $\phi_e = \pi BR_e^2$, $\phi_h = \pi BR_h^2$ are the magnetic fluxes threading the electron and hole rings, and $\phi_0 = \hbar c/\varepsilon$ is the flux quantum. $U_e(\Delta \theta)$ describes the Coulomb attraction between the electron and the hole, with $\varepsilon$ the dielectric constant of the semiconductor ring material, and the parameter $r = 2(R_e/R_h)/[1 + (R_e/R_h)^2]$ determines the shape and the strength of the Coulomb interaction. For $r \rightarrow 0 \ (R_h \gg R_e)$ the Coulomb potential as a function of $\Delta \theta$ is nearly flat, while for $r \rightarrow 1 \ (R_h \simeq R_e)$, the potential has a pronounced minimum at $\Delta \theta = 0$.

Even after these simplifications, $\hat{H}_{\text{exc}}(\theta_e, \theta_h)$ is not exactly solvable, at least analytically, due to the Coulomb interaction. In consequence, we have used the following direct numerical strategy: diagonalization of Eq.(1) in the non-interacting electron-hole pairs basis generated by the eigenstates of $\hat{H}_{\text{exc}}^0(\theta_e, \theta_h)$,

$$\hat{H}_{\text{exc}}^0(\theta_e, \theta_h)\psi_{\ell_e, \ell_h}^0(\theta_e, \theta_h) = E_{\ell_e, \ell_h}^0 \psi_{\ell_e, \ell_h}^0(\theta_e, \theta_h), \quad (4)$$

where

$$\psi_{\ell_e, \ell_h}^0(\theta_e, \theta_h) = \frac{1}{(2\pi)^{1/2}} e^{i \theta_e \ell_e + i \theta_h \ell_h}, \quad (5)$$

and

$$E_{\ell_e, \ell_h}^0(B) = \frac{\hbar^2}{2m_e R_e^2} \left( \ell_e \frac{\phi_e}{\phi_0} \right)^2 + \frac{\hbar^2}{2m_h R_h^2} \left( \ell_h \frac{\phi_h}{\phi_0} \right)^2, \quad (6)$$

where $\ell_e$ and $\ell_h \ (\pm 0, \pm 1, \pm 2, \ldots)$ are the electron and hole angular momentum quantum numbers, respectively. The non-interacting eigenstates of Eq.(5) can also be written in terms of $\Delta \theta$ and a new angular variable, given by

$$\theta_0 = (I_e \theta_e + I_h \theta_h)/I, \quad (7)$$

here $I_e = m_e R_e^2$, $I_h = m_h R_h^2$, and $I = I_e + I_h$ are the electron, hole, and total moments of inertia, respectively. $\theta_0$ is then a generalization of the so-call toroidal functions, and describes the translation of the whole exciton around the ring, while $\Delta \theta$ describes the internal (relative) exciton dynamics. Replacing in Eq.(5), we obtain,

$$\psi_{\ell_e, \ell_h}(\theta_0, \Delta \theta) = \frac{1}{2\pi} e^{i \theta_0 (\ell_e + \ell_h)} e^{i \Delta \theta (\ell_e - \ell_h)} / I. \quad (8)$$

The important point to note now is that as the Coulomb interaction only depends on $\Delta \theta$, the total angular momentum of the polarized exciton $L \equiv \ell_e + \ell_h$ remains a good quantum number even in the interacting regime; this is a consequence of the azimuthal rotational symmetry of the structured rings. Thus, the Hamiltonian matrix generated in the basis of Eq.(5) is block-diagonal, with each block corresponding to a given $L \ (= 0, \pm 1, \pm 2, \ldots)$. The numerical diagonalization of each block provides the eigenvalues and eigenstates of $\hat{H}_{\text{exc}}$, which we denote by $E_{L,n}(B)$ and $\varphi_{L,n}(\theta_0, \Delta \theta)$, respectively, with $n = 1, 2, \ldots$.

To obtain accurate exciton energies and wave-functions from the basis generated from Eq.(5), we truncate the basis by choosing an adequate set of quantum numbers $\ell_e$ and $\ell_h \ (\pm \ell_e \pm L)$ in each $L$ sub-space. This set is chosen starting from the couple $\ell_e$, $\ell_h$ which correspond to the magnetic-field dependent non-interacting ground-state energy. The size of the basis is chosen large enough such that the results do not depend on it. The only non-trivial point of this calculation scheme is the numerical evaluation of the matrix elements of $U_e(\Delta \theta)$ between the non-interacting eigenstates of Eq.(5). While formally these matrix elements can be written in term of the so-call toroidal functions, for its practical and accurate evaluation we have found more convenient the direct numerical integration over the one-dimensional variable $\Delta \theta$. Also, and considering the easy of its direct numerical evaluation, we do not recomment its evaluation through the large-size ring approximation, as we have found that it leads to some over-estimation of the exciton binding energy.

### III. Results

All the numerical results to be discussed below were obtained with material parameters appropriate for GaAs, that is: $m_e = 0.067 m_0$, $m_h = 0.268 m_0$, and $\varepsilon = 12.5$, with $m_0$ being the bare electron mass. The effective Bohr radius for the electron ($a_B$) is then equal to 98.7 Å. Also, we have assumed that $R_e \leq R_h$. 
Before proceed with the results a brief note on terminology is worth to be discussed. In principle, the numerical diagonalization of the exciton Hamiltonian results in a large number of eigenvalues, for each structured ring and magnetic field value. Our analysis, however, will be mainly concentrated on the lowest of these eigenvalues, the ground-state exciton. This ground-state exciton will be characterized in turn as belonging to the weak-interacting (WI) regime, or to the strong-interacting (SI) regime (see below). Excited exciton states will more properly considered as electron-hole pairs.

A. Weak Interacting Regime

In this regime, corresponding to structured rings of small size, the dominant contributions to \( H_{\text{exc}}(\theta_e, \theta_h) \) are the kinetic energy terms, with the Coulomb interaction acting as a small modification to the non-interacting results. Including accordingly \( U_c(\Delta \theta) \) in a perturbative way, we obtain

\[
E^{(1)}_{\ell_e, \ell_h}(B) = E^{(0)}_{\ell_e, \ell_h}(B) - \frac{2e^2}{\pi \varepsilon (R_e + R_h)} \frac{4R_e R_h}{(R_e + R_h)^2} K(x),
\]

with \( K(x) \) being the complete elliptic integral of the first kind. The second term on the r.h.s. of Eq.(9) corresponds to the matrix element \( U_c(m) \equiv \langle \psi^0_{\ell_e - m, \ell_h + m} | U_c | \psi^0_{\ell_e, \ell_h} \rangle \), with \( m = 0 \). This diagonal matrix element is the same for all couples of \((\ell_e, \ell_h)\) non-interacting electron-hole quantum numbers. Besides, in this regime, \( |U_c(0)| \gg |U_c(m \neq 0)| \), which supports the perturbative expression Eq.(9). According to this result, the exciton energy spectrum in the WI regime is the same as the non-interacting spectrum, but shifted rigidly by a negative constant.

We shown in Fig.1 the energy spectrum for a radial polarized exciton (RPE) in the WI regime, corresponding to a ring with \( R_e = 40 \, \text{Å}, \text{ and } R_h = 70 \, \text{Å} \). The top panel corresponds to the non-interacting spectrum, the lower panel to the interacting spectrum calculated exactly (numerically), and as given by the perturbative expression of Eq.(9). As can be seen from the results in the lower panel, the perturbative approximation nicely reproduces the main features of the numerical result, shifting the non-interacting spectrum towards negative energies by about 18 meV. It is interesting to note that the approximation works better for excited than for low-lying states. This is natural, as if the kinetic energy increases at constant Coulomb correction, the accuracy of the perturbative approach should increase. Beyond this simple first-order estimation are the several anticrossings which appear in the numerical results when two states with the same \( L \) approach each other as function of \( B \).

B. From the weak to the strong interacting regime

By approaching \( R_e \) and \( R_h \) to each other \((r \to 1)\), the Coulomb attraction between the hole and the electron is increasingly more important than the kinetic energy terms. We shown this crossover in Fig.2 where we display the RPE spectrum for decreasing values of \( R_h \), keeping \( R_e = 40 \, \text{Å} \). The more noticeable feature of these results is the progressive appearance of a “gap” among the low-lying and the excited states, for each \( L \) sub-space. Moving from top to bottom (left panel), the modification of the spectrum consist mainly in a progressive “deepening” of the given \( L \) low-lying state towards negative energies, while the excited states remains at energies close to zero. The right panel in Fig.2 corresponds to \( U_c(\Delta \theta) \), with the deeper one corresponding to \( R_h = 44 \, \text{Å} \) \((r = 0.995)\), and the shallow one to \( R_h = 60 \, \text{Å} \) \((r = 0.923)\). The straight horizontal lines denote the position of the lowest-lying states of the left panel (discounting the CM motion) for each size of the structured ring; once the kinetic energy of the CM motion has been subtracted the remaining energy becomes essentially i-
attractive potential lying states with magnetic flux, for three structured rings. Only the first low-lying states with \( L = 0 \) (full lines), \( L = 1 \) (dotted lines), and \( L = 2 \) (dashed lines) are shown. Right panel: Coulomb attractive potential \( U_c(\Delta \theta) \) for the three structured rings of the left panel, the horizontal bars in them correspond to the lowest lying state (see text).

dependent of \( L \) and \( B \) (see below). With this information at hand the meaning of the three split low-lying states of Fig.2c is clear: they correspond to “localized” exciton states, whose wave-function (internal component) is strongly localized around \( |\Delta \theta| \sim 0 \). This must be contrasted with the non-interacting exciton wave function of Eq.(8), whose internal component is uniformly distributed along its allowed values \( (|\Delta \theta| \leq \pi) \). Physically, this localization of the ground-state exciton wave function is driven by the attractive Coulomb interaction, which for \( r \to 1 \) is able of keep the electron and hole as close as possible, loosing kinetic energy but gaining Coulomb energy. An interesting feature of these results is that as more localized is a state, less dependence on the magnetic flux trapped by its individual components it shows. This issue will be discussed in detail in the next sub-section. We emphasize that the characterization of a state as “extended” or “localized” refers only to the internal component of the total exciton wave function. The CM component is always extended, as corresponds to a system with azimuthal rotational symmetry.

FIG. 2: Left panel, exciton energy spectrum versus electron magnetic flux, for three structured rings. Only the first low-lying states with \( L = 0 \) (full lines), \( L = 1 \) (dotted lines), and \( L = 2 \) (dashed lines) are shown. Right panel: Coulomb attractive potential \( U_c(\Delta \theta) \) for the three structured rings of the left panel, the horizontal bars in them correspond to the lowest lying state (see text).

C. Strong Interacting Regime

Increasing further the structured ring size, the system is driven to the SI regime, where the electron and hole strongly interact. Fig.3 corresponding to a ring with \( R_e = 100 \, \text{Å}, R_h = 120 \, \text{Å} \), displays clearly one set of localized \( L (= 0, 1, \text{and } 2) \) ground-states at negative energies, plus a bunch of closely energy spaced and strongly magnetic field dependent states at positive or close to zero energies. Fig.4 corresponds to an even larger structured ring, with the new feature of having two localized sets of states at negative energies, instead of one. The new localized set corresponds to the first-excited state of each \( L \).

An important feature of Figs.3 and 4 is the presence of a characteristic energy (negative but close to zero), above of which all states are extended. This energy is just \( U_c(\Delta \theta = \pm \pi) = -e^2/\varepsilon(R_e + R_h) \), corresponding to the minimum strength that the Coulomb potential can take in the constrained-ring geometry, and associated to the maximum possible inter-particle distance. For the ring of Fig.2c, \( U_c(\Delta \theta = \pm \pi) \approx -13.71 \, \text{meV} \), for the ring of Fig.3 \( U_c(\Delta \theta = \pm \pi) \approx -5.23 \, \text{meV} \), and about \(-1.83 \, \text{meV} \) for the ring of Fig.4. Conversely, all states below that energy are localized and their corresponding energies show a very weak dependence on \( L \) and \( B \), as we will discuss latter.

To analyze properly the results of the SI regime, it is useful to rewrite \( \hat{H}_{\text{exc}}(\theta_e, \theta_h) \) in term of the variables \( \theta_0, \Delta \theta \):

\[
\hat{H}_{\text{exc}}(\theta_e, \theta_h) = \hat{H}_{\text{exc}}(\theta_0, \Delta \theta) = \hat{H}_{\text{CM}}(\theta_0) + \hat{H}_{\text{int}}(\Delta \theta | 0) \]
is immediate, the solution of the cumbersome cyclic boundary-conditions for its associated combined magnetic and Coulomb contributions, and the of ε

The main achievement of this transformation is the ex-

and

and

FIG. 4: Left panel, exciton energy spectrum versus magnetic field for a ring with \( R_c = 300 \text{ Å}, R_h = 330 \text{ Å} \). Only the first low-lying states with \( L = 0 \) (full lines), 1 (dashed lines), and 2 (dotted lines) are shown. Right panel: Coulomb attractive ordinates (∆

\[ \hat{H}_{CM}(\theta_0) = \frac{\hbar^2}{2I} \left( -i \frac{\partial}{\partial \theta_0} + \frac{\phi_{CM}}{\phi_0} \right)^2, \quad (11) \]

and

\[ \hat{H}_{int}(\Delta \theta) = \frac{\hbar^2}{2I_{int}} \left( -i \frac{\partial}{\partial (\Delta \theta)} + \frac{\phi_{int}}{\phi_0} \right)^2 + U_c(\Delta \theta). \quad (12) \]

The main achievement of this transformation is the exact decoupling of the translational (\( \theta_0 \)) and relative coordinates (\( \Delta \theta \)). In equation above, \( \phi_{CM} = \pi(R_c^2 - R_h^2)B, I_{int} = I_iI_h/I, \) and \( \phi_{int} = \pi I_{int}B/\mu, \) with \( \mu = m_e m_h/(m_e + m_h). \)

Being \( \hat{H}_{exc}(\theta_0, \Delta \theta) \) the sum of the CM and internal contributions, the corresponding eigenvalues are given by

\[ E_{L,n}(B) = \frac{\hbar^2}{2I} \left( L + \frac{\phi_{CM}}{\phi_0} \right)^2 + \varepsilon_{L,n}(B), \quad (13) \]

and

\[ \varepsilon_{L,n}(\theta_0, \Delta \theta) = g_L(\theta_0)h_{L,n}(\Delta \theta), \quad (14) \]

with \( g_L(\theta_0) \) being eigenfunctions of \( \hat{H}_{CM}(\theta_0) \) and \( \varepsilon_{L,n}(B) \) and \( h_{L,n}(\Delta \theta) \) the eigenvalues and eigenfunctions of \( \hat{H}_{int}(\Delta \theta) \), respectively. While the solution of \( \hat{H}_{CM}(\theta_0) \) is immediate, the solution of \( \hat{H}_{int}(\Delta \theta) \) is not, due to its combined magnetic and Coulomb contributions, and the cumbersome cyclic boundary-conditions for its associated eigenfunctions. Some insight can be obtained, however, through the following gauge transformation of the internal component of the total exciton wave-function,

\[ h_{L,n}(\Delta \theta) = -\frac{1}{\Delta \theta} \frac{\partial}{\partial \phi_0} f_{L,n}(\Delta \theta). \quad (15) \]

The boundary conditions for the total exciton wave-function are easily established in term of the angular coordinates \( \theta_e, \theta_h : \varphi_{L,n}(\theta_e, \theta_h) = \varphi_{L,n}(\theta_e + 2\pi, \theta_h) \)

and \( \varphi_{L,n}(\theta_e, \theta_h + 2\pi) = \varphi_{L,n}(\theta_e + 2\pi, \theta_h + 2\pi) \). From these boundary conditions, it could be easily derived an equivalent set of boundary conditions in terms of \( \theta_0 \) and \( \Delta \theta: \varphi_{L,n}(\theta_0, \Delta \theta) = \varphi_{L,n}(\theta_0 + 2\pi I_e/I, \Delta \theta + 2\pi) = \varphi_{L,n}(\theta_0 + 2\pi I_h/I, \Delta \theta - 2\pi) = \varphi_{L,n}(\theta_0 + 2\pi, \Delta \theta) \). Finally, using Eqs.(14) and (15), the boundary conditions for the individual components of \( \varphi_{L,n}(\theta_0, \Delta \theta) \) are \( g(\theta_0) = g(\theta_0 + 2\pi), \) and

\[ f_{L,n}(\Delta \theta) = \exp [2\pi i \left( \frac{I_e L}{I} + \frac{\phi_{int}}{\phi_0} \right)] f_{L,n}(\Delta \theta + 2\pi), (16a) \]

\[ f_{L,n}(\Delta \theta) = \exp [2\pi i \left( \frac{I_h L}{I} - \frac{\phi_{int}}{\phi_0} \right)] f_{L,n}(\Delta \theta - 2\pi)(16b) \]

Replacing the anzatz of Eq.(15) in \( \hat{H}_{int}(\Delta \theta)\) of Eq.(16) we derive an effective equation that defines \( f_{L,n}(\Delta \theta) \); this equation is:

\[ -\frac{\hbar^2}{2I_{int}} \frac{\partial^2 f_{L,n}(\Delta \theta)}{\partial (\Delta \theta)^2} + U_c(\Delta \theta) f_{L,n}(\Delta \theta) = \varepsilon_{L,n}(B) f_{L,n}(\Delta \theta). \quad (17) \]

The wave-function \( f_{L,n}(\Delta \theta) \) satisfies then a magnetic-field independent one-dimensional Schrödinger-like equation. The magnetic field dependence of \( \varepsilon_{L,n}(B) \) is hidden now in the boundary conditions for \( f_{L,n}(\Delta \theta) \).

Summarizing, \( f_{L,n}(\Delta \theta) \) must satisfy the Schrödinger-like Eq.(17), plus the magnetic-field dependent boundary conditions of Eq.(16). Now, and this is the whole point, if the internal wave-function \( f_{L,n}(\Delta \theta) \) is strongly localized around \( \Delta \theta \approx 0 \), it makes not difference if we replace the complicated requirement of Eq.(16) by the “isolated well” boundary condition \( f_{L,n}(|\Delta \theta| \gg 1) \to 0 \). Proceeding by this way, the eigenvalues \( \varepsilon_{L,n} \) become \( L \) and magnetic-field independent, as in this regime the internal Hamiltonian and the boundary condition are both, \( L \) and magnetic-field independent. The approximation works better the more localized is the state, and can be sought as related to the tight-binding approximation employed in the calculation of the band-structure of crystalline solids. In this last case, and for an atomic orbital strongly localized on the scale of the lattice parameter, it makes no difference if one use the rigorous boundary condition imposed by the Bloch theorem or the “isolated atom” boundary condition. In both cases, the rigorous and the approximated calculation gives essentially the same result: a discrete level just at the energy of the atomic orbital of the isolated atom.

Accordingly, in this regime all the magnetic field dependence of the exciton energy comes essentially from the CM contribution. Thus, one can estimate the crossing points for exciton states with different total angular momentum such as \( L \to L + M \) from the condition
\( E_{L,n}(B) = E_{L+M,n}(B) \), neglecting the \( L \) and \( B \) dependence of \( \varepsilon_{L,n}(B) \). Using Eq.(13), we obtain thus for the crossing magnetic fields,

\[
B(L \to L + M) = \frac{\phi_0}{\pi(R_h^2 - R_e^2)} \left( L + \frac{M}{2} \right) . \quad (18)
\]

It is interesting to note, in this regime, the strong sensitivity of the crossing magnetic-fields to the difference between \( R_e \) and \( R_h \). In particular, the optically active (bright) exciton with \( L = 0 \) could be stabilized at larger magnetic fields by just moving to narrower structured rings. Using Eq.(18) for the low-lying states of Figs. 3, 4, we obtain for the ring of Fig. 4 that \( B(0 \to 1) \approx 14.69 \) T, and \( B(0 \to 2) \approx 29.92 \) T. Proceeding in the same way with the ring of Fig. 4 we obtain \( B(0 \to 1) \approx 3.48 \) T, \( B(0 \to 2) \approx 6.97 \) T, and \( B(1 \to 2) \approx 10.45 \) T. The good agreement between these estimations and the exact (numerical) results, confirms the hypothesis of the \( L \) and magnetic-field independence of \( \varepsilon_{L,n}(B) \). It is also worth to be noted that the crossing of the two sets of low-lying states (\( n = 1, 2 \)) in Fig. 4 takes place at the same crossing magnetic fields, as one expects if Eq.(18) be valid.

The exciton energies \( E_{L,n}(B) \) could be straightforwardly calculated from Eq.(13), once \( \varepsilon_{L,n}(B) \) is known. For the localized regime discussed above we provide in Appendix A an analytic (approximated) solution to the problem posed by the corresponding Eq.(17), which is useful for qualitative and semi-quantitative estimations of \( E_{L,n}(B) \). For instance, Eqs.(A.2) and (A.3) provide two useful estimations of \( \varepsilon_n \) (the \( L \) and \( B \) independent eigenvalues), and the number of bound localized states, respectively. It is interesting to note that this approximated analytical analysis always predicted the existence of a localized state. This is in agreement with the output of the much elaborated numerical results. It is worth of been mentioned that the naive application of the harmonic approximation does not work for the potential of Fig. 4. The reason for that is that \( U_e(\Delta \theta) \) is extremely deep and narrow (on the scale \( -\pi \leq \Delta \theta \leq \pi \)). In consequence, approximating it by an harmonic term in the bottom region, results in such a narrow parabolic potential that the ground-state energy of the corresponding harmonic oscillator (zero-point energy) is well above the “continuum” limit given by \( U_e(\Delta \theta = \pm \pi) \). In other words, the harmonic approximation gives not bound-states for the ground-state exciton for this structured ring, while the exact calculation yields two bound-states.

We display in Fig. 5 the Coulomb contribution to the ground-state energy, scaled by \( R_e/a_0^* \), at zero magnetic field and rings of several sizes. From top to bottom, \( R_e \to 0 \), \( R_e = 40 \) Å, \( 98.7 \) Å(\( a_0^* \)), \( 600 \) Å, and \( R_e \to \infty \).

\[
E_{\ell_{e/\pi},\ell_{h/\pi}}(B) = \frac{e^2 \delta_{\ell_{e/\pi},\ell_{h/\pi}}}{(1 + R_h/R_e)} \left[ \frac{4R_h/R_e}{(1 + R_h/R_e)^2} \right] . \quad (19)
\]

Note that scaled this way the contributions for different \( R_e^* \)s all collapses to a single curve. For \( R_h \) approaching \( R_e \) from above, the argument of the elliptic function tends to one and has a logarithmic divergence. The curve at the bottom corresponds to \( U_e(\Delta \theta = 0) \), scaled with the same factor \( R_e/a_0^* \). Similarity to the contribution of Eq.(19), \( R_e U_e(\Delta \theta = 0)/a_0^* \) collapses to a single curve for all values of \( R_e^* \)s. In this case, for \( R_h/R_e \to 1 \), the divergence is of the type \( (R_h - R_e)^{-1} \). The four remaining intermediate curves, correspond from top to bottom to \( R_e = 40 \) Å, \( R_e = a_0^* \), \( R_e = 300 \) Å, and \( R_e = 600 \) Å. They have been obtained from the numerical results. The result of Eq.(19) could be considered as giving the limiting value of the Coulomb contribution in the WI regime of \( R_e \to 0 \). This explains why the closer curve to this one is that corresponding to the smallest considered rings, \( R_e = 40 \) Å. In a similar vein, the curve corresponding to \( U_e(\Delta \theta = 0) \) could be considered as providing the limiting value of the Coulomb contribution when \( R_e \to \infty \), i.e. well inside in the SI regime. In this extreme limit, the exciton behaves as a classical particle, its energy given by the minimum of the Coulomb potential at \( \Delta \theta = 0 \). This explains why the curves for increasing values of \( R_e \) approach progressively this limiting value.

As an accurate way of characterize the radial polarized excitons in structured rings we have also calculated the expectation value of \( \Delta \theta^2 \), in the ground-state of the system at zero magnetic field. The results are presented in...
The SI regime, respectively.

It is interesting to note that for intermediate values of the relative angular coordinate, that describes the internal dynamics of the polarized exciton, however, are completely different. In our case, the localized states correspond to a tightly-bound electron-hole pair, whose relative coordinate is essentially "frozen" at zero, but whose center of mass coordinate rotates freely around the structured ring.

We have found that the ground-state of polarized excitons can be well characterized in two extreme regimes: i) The weak interacting regime, where the electron and hole kinetic energies are larger than the Coulomb interaction, and ii) The strong interacting regime, where the exciton ground-state properties are dominated by the Coulomb electron-hole attraction.

For the weak interacting regime we have provided an analytical approximation. According to this, the weakly interacting excitonic spectrum could be obtained by shifting rigidly the non-interacting spectrum by a negative constant. The constant depends only on the size of the structured rings, but is state-independent. The ground-state exciton WI shows discernible Aharonov-Bohm oscillations with the magnetic field. In this regime it has been predicted the alternate of "bright" \((L = 0)\) and "dark" \((L \neq 0)\) exciton ground-states as a function of the magnetic field. However, for GaAs material parameters, we have found that the rigorous inclusion of the Coulomb interaction removes such effect, and once the \(L = 0\) ground-state crosses with the \(L = 1\) ground-state, it does not become again the ground-state.

The ground-state in the strong interacting regime depends on the magnetic field only through the phase accumulated by the CM angular coordinate, which represents the translation as a whole of the polarized exciton. On the other side, the relative angular coordinate, that describes the internal dynamics of the polarized exciton, remains essentially "frozen" around zero. We have provided also an analytical approximation for this regime.

We have found almost invariably, the simultaneous presence of localized and extended states. This is somewhat similar to the findings of Ref.\[14\], that have shown a similar excitonic spectrum for the case of a ring with electric and magnetic fields applied along and perpendicular to the ring plane respectively, in absence of Coulomb interaction effects. The rotational and internal structure of the exciton, however, are completely different. In the situation of Ref.\[14\], the localized states are induced by the applied electric field, that pushes and localizes the electron and hole to opposite sides of the ring. Using our notation and terminology, this kind of exciton has both, the rotational and internal degree of freedom frozen, with \(\theta_0\) fixed by the electric field direction, and \(|\Delta \theta| \approx \pi\). In our case, the localized states correspond to a tightly-bound electron-hole pair, whose relative coordinate is essentially "frozen" at zero, but whose center of mass coordinate rotates freely around the structured ring.
A. APPENDIX

We provide in this Appendix an analytic (approximated) solution to the problem posed by the corresponding Eq.(17), which is useful for qualitative estimations of $E_{L,n}(B)$ in the localized regime. That is, neglecting the dependence of $\varepsilon_{L,n}(B)$ on $L$ and $B$; these approximated eigenvalues will be denoted by $\varepsilon_n$. With this aim, we have found that $U_c(\Delta \theta)$ is well approximated by

$$U_c(\Delta \theta) \approx V_c(\Delta \theta) = -\frac{\alpha^2}{\varepsilon} \frac{1}{|R_e - R_h|} - \frac{V_0}{\cosh(\alpha \Delta \theta)},$$

where $V_0 = \alpha^2 \left( \frac{1}{|R_e - R_h|} - \frac{1}{|R_e + R_h|} \right) / \varepsilon > 0$, and $\alpha$ is a dimensionless parameter to be determined latter. The advantage of $V_c(\Delta \theta)$ over $U_c(\Delta \theta)$ is that its exact analytical solution is known\textsuperscript{30}. The eigenvalues associated with the bound solutions are given by

$$\varepsilon_n = \frac{\alpha^2 \hbar^2}{8 I_{int}} \left[ 1 - 2n + \left( 1 + \frac{8 \mu V_0}{\alpha^2 \hbar^2} \right)^{1/2} \right]^2,$$

while the eigenfunctions are given in terms of the hypergeometric function\textsuperscript{31}. It should be noted that Eq.(A2) always provided a bound state, corresponding to $n = 1$. The number of bound states is however finite, and given by the condition

$$n_{max} < \frac{1}{2} \left[ 1 + \left( 1 + \frac{8 \mu V_0}{\alpha^2 \hbar^2} \right)^{1/2} \right].$$

In Eq.(A.2), everything is known, except $\alpha$. In our case, as we have from our full diagonalization scheme the exact value of $\varepsilon_1$, we have adopted the criterium of choose $\alpha$ such that it reproduces exactly the numerical value of $\varepsilon_1$, through Eq.(A2). This produces the value $\alpha = 5.458$ for the structured ring of Fig. 4, and the $V_c(\Delta \theta)$ shown as a dashed line in the right panel. This “optimum” choice of $\alpha$ is reflected in the fact that $U_c(\Delta \theta)$ and $V_c(\Delta \theta)$ are identical right at the energy where $\varepsilon_1$ falls. We have checked, however, that the value of $\varepsilon_1$ is not sensitive to the precise value of $\alpha$ and that any other reasonable criterias for its determination (least-square fitting of $U_c(\Delta \theta)$, etc.), works so well as our “optimum” fitting.
