ABSTRACT

In this study, we focus on the impact of accretion from protoplanetary discs on the stellar evolution of AFG-type stars. We used a simplified disc model that was computed using the Two-Pop-Py code, which contains the growth and drift of dust particles in the protoplanetary disc, to model the accretion scenarios for a range of physical conditions for protoplanetary discs. Two limiting cases were combined with the evolution of stellar convective envelopes that were computed using the Garstec stellar evolution code. We find that the accretion of metal-poor (gas) or metal-rich (dust) material has a significant impact on the chemical composition of the stellar convective envelope. As a consequence, the evolutionary track of the star diverts from the standard scenario predicted by classical stellar evolution models, which assume a constant and homogeneous chemical composition after the assembly of the star is complete. In the case of the Sun, we find a modest impact on the solar chemical composition. Indeed, the accretion of metal-poor material reduces the overall metallicity of the solar atmosphere and it is consistent, within the uncertainty, with the solar Z reported by Caffau et al. (2011, Sol. Phys., 268, 255), but our model is not consistent with the measurement by Asplund et al. (2009, ARA&A, 47, 481). Another relevant effect is the change of the position of the star in the colour–magnitude diagram. By comparing our predictions with a set of open clusters from the Gaia DR2, we show that it is possible to produce a scatter close to the TO of young clusters that could contribute to explaining the observed scatter in CMDs. Detailed measurements of metallicities and abundances in the nearby open clusters will additionally provide a stringent observational test for our proposed scenario.

Key words. planet-star interactions – Sun: abundances – stars: abundances – stars: fundamental parameters – protoplanetary disks

1. Introduction

Over recent decades, major progress has been made in studies of protoplanetary (PP) discs through modelling (e.g. Dullemond et al. 2002; Dullemond & Dominik 2004; Oka et al. 2011; Birmelst et al. 2011, 2012; Bitsch et al. 2013; Baillie et al. 2015) and observations (e.g. ALMA Partnership 2015). It is widely recognised that discs are ubiquitous around young stars and a significant fraction of these have been observed with facilities such as ALMA (e.g. Clarke et al. 2018; Fedele et al. 2018; Favre et al. 2019; van Terwisga et al. 2019; Diep et al. 2019; Nazari et al. 2019), Gemini (e.g. Salyk et al. 2019), VLA (e.g. Macias et al. 2018), and SPHERE (e.g. van Boekel et al. 2017; Avenhaus et al. 2017, 2018). However, the relationships between disc formation and the presence or absence of planets is still poorly understood. While the gaps and rings detected with large surveys such as ALMA are thought to be associated with planet formation, the system named PDS 70 still remains the only confirmed detection of a planet in a PP disc (Metcalf et al. 2004; Hashimoto et al. 2012; Keppler et al. 2018). Nonetheless, surveys for planets orbiting solar-like stars have demonstrated that planets are common and may even even outnumber stars in the Milky Way galaxy (e.g. Mayor et al. 2011; Cassan et al. 2012; Mulders et al. 2018).

The formation of PP discs has an important, as yet unexplored, effect on the formation and evolution of their central stars. Canonical 1D stellar structure models see the evolution of stars from an initially bright and expanded object along the Hayashi track to the asymptotic giant branch (AGB) or white dwarf (WD) phase, assuming, however, that stellar evolution proceeds in isolation (e.g. Pietrinferni et al. 2004; Weiss & Schlatt 2008; Paxton et al. 2011). Yet the population statistics of exo-planets and discs clearly indicate that this assumption is not justified. One important aspect of the coupled star-planetary evolution is the accretion of the dust and gas from the disc onto the central star. This effect could be especially significant during the early phases of stellar evolution, from a few to tens of Myr, especially for \( M \gtrsim 1 M_\odot \), when the star’s convective envelope evolves rapidly. In a recent study, Kunimoto et al. (2018) highlighted the substantial effect that the accretion from the PP disc has on the pre-MS star. However, they focussed on the accretion of metal-poor material, assuming that refractory elements are locked up in planets or planetesimals. Metal-rich accretion in the form of planet engulfment has been studied by Tognelli et al. (2016) and Serenelli et al. (2011) explored the effects of accretion onto the early Sun. However, the latter study employed arbitrary \( M \)-composition scenarios and no attempt was made to probe different regimes of the stellar parameter space (metallicities, ages) other than the Sun. Apart from this, strong evidence has been established for the accretion of planetesimals orbiting about WDs (e.g. Vanderburg et al. 2015; Gänssicke et al. 2019) and Kama et al. (2015) demonstrated that the photospheric composition of A-type stars with protoplanetary discs correlates directly with the presence of dust-poor
cavities in their discs. Also, the differences between abundance-condensation temperature trends of the Sun and sun-like stars can potentially be explained by the presence of planets or accretion of planetesimals (e.g. Meléndez et al. 2009; Bedell et al. 2018).

In this study, we model the evolution of stars of one to three solar masses to explore the influence of accretion from the PP disc on the metallicity in stellar convective envelopes and on the star’s effective temperature and metallicity, respectively. This work is motivated by two observational findings: (1) the discrepancy between the predictions of Standard Solar Model (SSM) for the photospheric solar abundances and helioseismic predictions (e.g. Serenelli et al. 2009) and (2) the putative spreads in the characteristic radius of the disc, \( r_c \). Observations of PP discs (e.g. Flaherty et al. 2016; Dullemond et al. 2018) show that the plausible range of \( r_c \) values closes in around \( 10^{-4} \)–\( 10^{-2} \).

The fragmentation threshold velocity \( v_{\text{frag}} \) is the relative velocity that defines whether the dust grains will grow by sticking together or fragmenting. Collision leads to the fragmentation of grains if they move with velocities greater than \( v_{\text{frag}} \). Our choice of the fragmentation velocity is motivated by laboratory experiments of dust and water ice grains (e.g. Gundlach & Blum 2015), however these show that the exact fragmentation velocity depends on the shape and composition of the dust grains and this is still under debate (Musiolik & Wurm 2019; Steinpilz et al. 2019). The influence of both parameters, \( v_{\text{frag}} \) and \( \alpha \), on the chemical evolution of PP discs is discussed in Sect. 2.4.

The temperature structure of the disc is estimated by taking passive irradiation and viscous heating into account. TPP also includes radial drift of dust grains that implies a faster accretion of solids onto the star and, hence, the decrease of dust mass in the disc over time. This is supported by observational studies of disc masses across different evolutionary stages, which favour strong trends where younger discs possess significantly larger dust mass compared to older, more evolved, discs (e.g. Anderl et al. 2017; Williams et al. 2019). Pressure bumps in the disc may act as traps for inward moving dust particles (Whipple 1972), thereby slowing down the drift of grains and prolonging the lifetime of dust. However, only a small fraction of discs (5–10% of all discs) contain large dust masses after 1 Myr (Williams et al. 2019), implying that a large fraction of discs must have lost their dust component onto the central star. Therefore, we do not include pressure bumps in the model.

The TPP code requires a number of input parameters to be defined: mass \( (M) \), effective temperature \( (T_{\text{eff}}) \), and radius \( (R) \) of the star; characteristic radius \( (r_c) \), initial mass \( (M_{\text{initial}}) \), and dust-to-gas ratio \( (\rho/g) \) of the disc; density of the dust particles \( (\rho_g) \); size of the smallest dust grains \( (a_0) \); fragmentation velocity \( (v_{\text{frag}}) \); and turbulence parameter \( (\alpha) \). The geometric size of the disc is given by the minimum \( r_{\text{min}} \) and maximum \( r_{\text{max}} \) radii, respectively. Our adopted values of these parameters are given in Table 1.

The dust-to-gas ratio corresponds to the ratio of the Sun (Grevesse & Noels 1993). The disc mass of 0.1 \( M \) corresponds to a typical gas mass of young protoplanetary discs (Andrews et al. 2010). The critical radius of the disc of 200 AU corresponds to a large disc, as they are seen in the DSHARP (Andrews et al. 2018) survey. The choices of stellar parameters – \( T_{\text{eff}}, M \), and \( R \) – are described in Sect. 2.3.

2.2. Mass and chemistry of the accreted material

The TPP code does not conserve mass. The main mechanism for mass loss from the disc is the accretion of material onto the central mass, and only a minuscule fraction of less than 0.1% is lost through the outermost boundary of the disc. This allows us to compute the properties of accreted matter as follows.

The TPP code supplies us with surface densities, \( \Sigma_g \) for gas and \( \Sigma_d \) for dust as a function of the disc radius and time. We

\footnote{The characteristic radius defines the effective size of the disc by setting an exponential cut-off in the disc’s gas and dust density}
Table 1. Input parameters of TPP simulation.

| Parameter       | Value               | Unit |
|-----------------|---------------------|------|
| $\alpha$        | $10^{-4}$–$10^{-2}$ | –    |
| $v_{\text{frag}}$ | $10^2$–$10^3$      | cm s$^{-1}$ |
| $d/g$           | 0.01965             |      |
| $M$             | depending on alpha  |      |
| $M_{\text{disc}}$ | 0.1 $M$            | $M_\odot$ |
| $T_{\text{eff}}$ | stellar models      | K    |
| $R$             | stellar models      | $R_\odot$ |
| $r_{\text{min}}$ | 0.05 (default)      | AU   |
| $r_{\text{max}}$ | 3000 (default)      | AU   |
| $r_c$           | 200                 | AU   |
| $\rho_s$        | 1.156 (default)     | g cm$^{-3}$ |
| $a_0$           | $10^{-5}$           | cm   |

Notes. The range of $\alpha$ and $v_{\text{frag}}$ is further discussed in Sect. 2.4. We note that $M$, $R$, and $T_{\text{eff}}$ refer to the parameters of a star, not of the disc. The initial stellar mass $M$ has to be changed according to alpha to ensure that it approaches 1 $M_\odot$ at the end of the simulation.

We compute the mass of each phase, $M_d$ is mass of the dust and $M_g$ the mass of the gas at a given point in time, by integrating over the area of the disc:

$$M_{d,g}(t) = \alpha \int_{r_{\text{min}}}^{r_{\text{max}}} r \Sigma_{d,g}(t, r) \, dr,$$

where $r_{\text{min}}$ and $r_{\text{max}}$ are defined in Table 1. The evolution of $M_{d,g}$ is driven by the accretion of material onto the star, therefore, we simply assume that the differences between the time steps $i$ and $i+1$ represent the total accreted mass at $i+1$. We note that the initial $M_{d,g}$ at time zero do not depend on $r_{\text{min}}$ and $r_{\text{max}}$, but have been set by $M_{\text{disk}}$ and $d/g$.

We assume that the metallicity of the dust phase is exactly one and the metallicity of the gas phase is exactly zero. Hence, we can calculate the metallicity of the material accreted between the timesteps as follows:

$$Z_{\text{accr}} = \frac{M_d}{M_d + M_g}.$$

We find that this approach is appropriate in the context of our work as meteorites in the solar system are known to contain negligible fractions of H and He (Lodders 2003). Setting more precise constraints on the evolution of the disc chemistry requires a detailed chemical network that includes the radial drift and growth of these grains, as well as the evaporation and condensation of these grains at ice lines (e.g. Booth et al. 2017). However, providing a detailed model of the exact composition of the material is beyond the scope of this work.

2.3. Stellar evolution models

Stellar models were computed with the Garstec code (Weiss & Schlattl 2008). We calibrated the mixing length parameter, initial metallicity, and helium abundance on the Sun using the solar metal abundance given by Grevesse & Sauval (1998) ($\alpha(\text{Fe}) = 7.50$, $(Z/X)_{\text{phot}} = 0.0229$ dex). From this calibration, we obtain $\alpha_{\text{MLT}} = 1.811$, initial solar helium abundance $Y_{\text{ini}} = 0.26896$, and metallicity $Z_{\text{ini}} = 0.01876$. Due to the effects of microscopic diffusion, the initial solar composition corresponds to $[\text{Fe}/\text{H}] = +0.06$.

For the present work, we computed a dense grid of stellarm models in the mass range $0.6 M_\odot \leq M \leq 6 M_\odot$ in steps of 0.02 up to 3 solar masses and in steps of 0.04 from 3 to 6 solar masses. The initial composition of the models is computed assuming a cosmic helium-to-metal enrichment ratio of $\Delta Y/\Delta Z = 1.1$ anchored to the initial solar composition and a cosmological $Y_{\text{BBN}} = 0.2487$ (Steigman 2007).

Figure 1 shows the evolution of the mass inside the convective envelope $M_{\text{CE}}$ for stars of different initial mass ($M_{\text{ini}}$) during the early stages of evolution. The convective envelope recedes faster for more massive stars. $M_{\text{CE}}$ on the main sequence depends primarily on the $T_{\text{eff}}$ of the star, that is, on the stellar mass and metallicity. For solar metallicity, which is indicative of the models used in this work, stars above 1.5 $M_\odot$ lose their convective envelopes completely (except for a very thin envelope $10^{-5} M_\odot$), whereas convective envelopes for a solar mass never recede below 0.02 $M_\odot$ during the star’s life on the MS.

2.4. Accretion histories

The two key parameters that impact the evolution of PP discs are the turbulent viscosity parameter $\alpha$ (Shakura & Sunyaev 1973) and the fragmentation velocity $v_{\text{frag}}$ that sets the lower limit for the growth of dust. Since it is not possible to set tighter constraints on these parameters at this stage, we explore a range of values for both $\alpha$ and $v_{\text{frag}}$ covering the parameter space reported in the literature. In particular, we vary $v_{\text{frag}}$ from $10^2$ to $10^3$ cm s$^{-1}$ and $\alpha$ from $10^{-4}$ to $10^{-2}$ (Sect. 2.1).

The temporal evolution of the mass accretion rate and of the metallicity in the accreted matter for four different initial mass combinations of the two parameters are shown in Fig. 2. Clearly, even within the limited parameter space explored in this example, we find a broad variety of accretion scenarios. The mass accretion rates range from $10^{-10}$ to $10^{-8} M_\odot$ yr$^{-1}$ and show very different behaviours, depending on the values of $\alpha$ and $v_{\text{frag}}$. A high $\alpha$ parameter, meaning a very turbulent disc, leads to rapid gas accretion and, therefore, to a low metallicity of the accreted material. In the opposite case, low $\alpha$ slows gas accretion down, which allows the dust to dominate the early accretion. This effect is caused by the changing grain growth and drift properties with different viscosities. At low viscosity, grains grow larger and thus drift faster inwards, leading to a dust dominated accretion history, while at a high viscosity, grains stay small (due to the higher turbulent velocities limiting their growth) and, thus, they...
We assume instantaneous accretion and mixing throughout the convective envelope of a star at a fixed time, \( t \). Since the convective envelope is monotonically receding, this gives the limiting change in metallicity for all accretion histories within a timescale, \( t \). We also neglect perturbations of the mechanical equilibrium structure of the star that could possibly be caused by the transfer of energy and momentum from the disc.

In each of the two afore-mentioned scenarios, the final metallicity of the convective envelope is given by:

\[
Z_{CE,\text{max}} = \frac{M_{CE}(t)Z_{\text{ini}} + M_{\text{disc}}Z_{\text{ini}}}{M_{CE}(t) + M_{\text{disc}} Z_{\text{ini}}} \quad \text{(3)}
\]

\[
Z_{CE,\text{min}} = \frac{M_{CE}(t)Z_{\text{ini}}}{M_{CE}(t) + M_{\text{disc}} (1 - Z_{\text{ini}})} \quad \text{(4)}
\]

where \( M_{CE} \) is the mass of the stellar convective envelope, \( M_{\text{disc}} \) is the initial mass of the disc before accretion, \( t \) the time at which accretion occurs and \( Z_{\text{ini}} \) is the initial metallicity, which is assumed to be the same for the star and its disc. Equation (3) describes metal-rich accretion and Eq. (4) describes metal-poor accretion.

We ought to keep in mind that in each of the two scenarios, the mass of the star itself changes. This has to be accounted for when comparing the results with observations from clusters, as we do in the next section.

### 3. Results

We begin the discussion with a comparison of our predictions for the Sun with its present-day photospheric chemical composition (Sect. 3.1). We then provide quantitative predictions for the accretion-induced changes in the surface properties of stars across a range of ages and metallicities. We compare our model predictions with the observed colour-magnitude diagrams (CMD) of open clusters in the Gaia DR2 (Sect. 3.2) and discuss whether accretion from the PP discs is a viable mechanism to explain the broad MS turn-offs in clusters.

#### 3.1. The peculiar composition of the Sun

It is known that the chemical composition of the Sun is somewhat peculiar. The Sun appears to be more metal-poor in refractory elements compared to stars in the solar neighbourhood (Ramírez et al. 2014; Adibekyan et al. 2014; Nissen 2016; Bedell et al. 2018). Recently, the composition of the solar photosphere was revised using 3D non-local thermodynamic equilibrium (NLTE) models by Asplund et al. (2005, 2009) and Caffau et al. (2011). The new metallicity, and in particular the oxygen abundance, is significantly lower than that given in the old compilation from Grevesse & Sauval (1998), who relied on simpler 1D LTE models. The standard solar models that employ the 3D NLTE abundances yield a present-day structure for the Sun that is significantly different from inferences based on direct helioseismology measurements (e.g. Bahcall et al. 2005; Castro et al. 2007; Serenelli et al. 2009; Buldgen et al. 2017). Various theories have been put forward to explain the mismatch, including energy transport by dark matter particles in the Sun or resonant emission of transversely polarised hidden photons (see e.g. Vincent et al. 2015; Sokolov 2020). We explore whether our accretion scenario has the potential to help resolve the problem.

The Sun was fully convective for \( \approx 2 \) Myr during the first stages of its life. The lifetime of the solar nebula is constrained to 3–4 Myr by meteorites (Connelly et al. 2012; Wang et al. 2017).
We model accretion from the proto-solar disc onto the early Sun assuming that accretion happened within 3 Myr and the protoplanetary disc mass was 10% of the solar mass. Applying the two limiting case scenarios, as described in Sect. 2.5, we find that solar photospheric metallicity Z could have indeed changed substantially, namely, by ~10% under the influence of accretion. In the case of metal-rich accretion (Eq. (3)), the present-day metallicity of the solar photosphere is $Z_{\text{max}} = 0.02004$, which is 11.3% above the initial value. The initial solar mass should have been roughly 0.998 $M_\odot$. In the case of metal-poor accretion (Eq. (4)), we obtain a lower limit on the surface metallicity of $Z_{\text{min}} = 0.01627$, which is 9.61% below the initial solar metallicity. The initial solar mass should have been roughly 0.911 $M_\odot$. Thus, the change in the photospheric metallicity of the Sun is significant enough to impact the discussion of the solar modelling problem (Castro et al. 2007; Guzik & Mussack 2010; Serenelli et al. 2011; Buldgen et al. 2019). The estimate given by Asplund et al. (2009), that is, $Z = 0.0134$, cannot be explained by our models. However, the solar metallicity reported by Caffau et al. (2011), $Z = 0.0153$, is, within the uncertainties of the data and consistent with our metal-poor accretion model. This implies that our scenario could, in principle, explain the mismatch between the present-day composition of the Sun and the SSMs-constrained using helioseismology, alleviating the need for other, more elaborate explanations. Detailed solar model calculations accounting for the specific accretion histories can be used in order to confirm this.

### 3.2. Influence on observable properties of stellar populations

As discussed earlier in this paper, the accretion of matter from the PP disc onto the star changes its total mass and metallicity. For low-mass stars, the material is (almost instantly, compared to evolutionary timescales) diluted across the entire convective envelope, hence, the metallicity effect strongly depends on the size of the CE. The higher the mass of a star, the more pronounced the changes with respect to the initial abundances. This constant addition of matter and re-adjustment of the chemical composition in the CE, furthermore, leads to changes in the physical structure of a star and its surface properties, and, consequently, in the position of a star in the plane of observable quantities, $\log g$ and $T_{\text{eff}}$.

In what follows, we explore the consequences of stellar evolution modulated by accretion from PP discs for the position of stars in colour-magnitude diagrams. We quantify the influence of accretion on evolutionary tracks of stars with different masses and initial metallicities and assess the modulation of surface metallicity against age. We also compare the predictions of our models with several Galactic open clusters, for which precision astrometry from Gaia DR2 is now available, in order to test the viability of our scenario.

#### 3.2.1. Observations of open clusters

In this work, we select all nearby open clusters with the age of $\leq 0.8$ Gyr released with the Gaia DR2 (Gaia Collaboration 2018). In addition, we exclude some of the clusters that contain too few members. This leaves us with six open clusters with ages from $\sim 70$ Myr ($\alpha$ Per) to $\sim 800$ Myr (Hyades) at heliocentric distances of $\sim 50$ to $\sim 250$ kpc (Gaia Collaboration 2018). Their basic parameters are listed in Table 2. The cluster membership was determined via an iterative procedure from the analysis of the positions of stars, their proper motions, and parallaxes resulting in a very reliable classification (Gaia Collaboration 2018, their Appendix A.1 and Table A.2). The proximity of clusters is essential, as, owing to the high accuracy of parallaxes and proper motions, this minimises the problem of foreground/background contamination. We illustrate the uncertainties of Gaia measurements for two clusters in our sample, Praesepe and Blanco 1, in Figs. A.1 and A.2 in the Appendix.

The clusters are shown in Fig. 3. Symbols represent the data from Gaia DR2. Representative isochrones are over-plotted. These isochrones are not to be viewed as best-fit isochrones, as we made no attempt to fit them statistically, but chose to show a representative model that describes the cluster main-sequence. This procedure does not impact our results and conclusions because we are only interested in the dispersion of stars at the cluster MSTO and this parameter does not depend on the choice of the model as long as the cluster’s main-sequence is reproduced.

#### 3.2.2. Impact of protoplanetary disc accretion on cluster morphology

It is interesting to note that despite an overall consistency between the observed positions of stars in the clusters and the theoretical isochrones, there is a significant number of outliers in the observed data and their fraction increases at the MSTO. This peculiarity has already been reported in the literature (Mackey & Broby Nielsen 2007; Marino et al. 2018a; Cordoni et al. 2018) and termed extended main-sequence turn-off (hereafter, eMSTO). A number of physical scenarios have been put forward to explain these, such as rotation (Bastian & De Mink 2009; Dupree et al. 2017; Bastian et al. 2018; Marino et al. 2018b; Sun et al. 2019) and multiplicity (e.g. D’Antona et al. 2016; Cordoni et al. 2018). Here we explore whether this peculiar effect can be potentially explained with our scenario of accretion from protoplanetary discs.

Using Eqs. (3) and (4), we can compute minimum and maximum metallicities as a function of $M_{\text{disc}}$ and $M_{\text{star}}$ assuming some $Z_{\text{min}}$. Linking metallicity to stellar mass we computed two extreme isochrones for each cluster of a given age and metallicity. To probe the effect of the disc lifetime, we then explored two cases. One case represents the accretion up until the age of 1 Myr, the other corresponds to extended accretion up to 3 Myr, which is equivalent to a longer-lived PP disc.

The results of our model for all our clusters are shown in Fig. 3, where the orange line corresponds to the fiducial cluster isochrone, whereas the shaded area and the dotted lines represent outliers in the observed data and their fraction increases at the MSTO. This peculiarity has already been reported in the literature (Mackey & Broby Nielsen 2007; Marino et al. 2018a; Cordoni et al. 2018) and termed extended main-sequence turn-off (hereafter, eMSTO). A number of physical scenarios have been put forward to explain these, such as rotation (Bastian & De Mink 2009; Dupree et al. 2017; Bastian et al. 2018; Marino et al. 2018b; Sun et al. 2019) and multiplicity (e.g. D’Antona et al. 2016; Cordoni et al. 2018). Here we explore whether this peculiar effect can be potentially explained with our scenario of accretion from protoplanetary discs.

Using Eqs. (3) and (4), we can compute minimum and maximum metallicities as a function of $M_{\text{disc}}$ and $M_{\text{star}}$ assuming some $Z_{\text{min}}$. Linking metallicity to stellar mass we computed two extreme isochrones for each cluster of a given age and metallicity. To probe the effect of the disc lifetime, we then explored two cases. One case represents the accretion up until the age of 1 Myr, the other corresponds to extended accretion up to 3 Myr, which is equivalent to a longer-lived PP disc.

The results of our model for all our clusters are shown in Fig. 3, where the orange line corresponds to the fiducial cluster isochrone, whereas the shaded area and the dotted lines represent outliers in the observed data and their fraction increases at the MSTO. This peculiarity has already been reported in the literature (Mackey & Broby Nielsen 2007; Marino et al. 2018a; Cordoni et al. 2018) and termed extended main-sequence turn-off (hereafter, eMSTO). A number of physical scenarios have been put forward to explain these, such as rotation (Bastian & De Mink 2009; Dupree et al. 2017; Bastian et al. 2018; Marino et al. 2018b; Sun et al. 2019) and multiplicity (e.g. D’Antona et al. 2016; Cordoni et al. 2018). Here we explore whether this peculiar effect can be potentially explained with our scenario of accretion from protoplanetary discs.

### Table 2. Nearby open clusters used in this work.

| Cluster     | Parallax (mas) | Distance (pc) | Metallicity (Z) |
|-------------|----------------|---------------|-----------------|
| Hyades      | 21.052         | 47.5          | 0.020           |
| Coma Ber    | 11.640         | 85.9          | 0.017           |
| Pleiades    | 7.364          | 135.8         | 0.017           |
| Praesepe    | 5.371          | 186.2         | 0.020           |
| a Per       | 5.718          | 174.9         | 0.020           |
| Blanco 1    | 4.216          | 237.2         | 0.017           |

Notes. Data adopted from Gaia Collaboration (2018).
Fig. 3. Hertzsprung–Russell diagrams of nearby open clusters from Gaia DR2. The blue shaded area depicts the range of Bp–Rp that could be explained by different accretion histories for a disc lifetime of 1 Myr. The area between the two dotted blue lines shows the same effect, but for a disc lifetime of 3 Myr.

The range of possible displacements of stars within this cluster given the assumed accretion history, that is, short- and long-lived PP discs. We overplot the observed clusters with very accurate parallaxes and photometry from Gaia DR2. Accretion of matter from the PP disc leads to changes in the evolutionary track of a star and, consequently, in the position of a star in the Bp–Rp – $M_G$ plane$^3$. Stars that experienced the accretion of metal-poor material (gas) from their discs are shifted to the left, towards bluer colours (or higher $T_\text{eff}$), whereas the objects that underwent the accretion of metal-rich material are displaced to the right, towards redder colours (or lower $T_\text{eff}$). The displacement is not the same along the isochrone because it depends on the extension of the convective envelope and, hence, on the stellar mass.

The net result is that the cumulative distribution of stars in a cluster can no longer be described by a single isochrone. Instead, stars show a significant dispersion around the characteristic locus that corresponds to a best-fit model. This scatter gradually increases and attains maximum at the cluster MSTO point because MSTO stars have the smallest convective envelopes. Extended accretion, as, for example, caused by longer-lived discs, increases the intra-cluster MSTO scatter. Consequently, the loci corresponding to 3 Myr discs are significantly wider compared to the loci computed for shorter-lived 1 Myr discs.

A comparison of our results with the observations of nearby open clusters shows that the MSTO scatter predicted by our model indeed matches the data. Every cluster studied in this work, except Blanco 1, shows the characteristic observed dispersion of $\sim 100–200$ K at the MSTO (corresponding to 0.05 mag in Bp–Rp), which is qualitatively consistent with the simulated loci (Fig. 3). The theoretical MSTO spread is large for younger clusters, but it is not as significant for older systems. The observed dataset for Blanco 1 is too sparse and it does not allow to quantify its MSTO dispersion. At this stage, it is not possible to distinguish between long- or short-lived discs because the samples of cluster members are still very small and selection functions are difficult to quantify. Altogether, this may lead to a biased measure of the observed MSTO width. Nonetheless, our results provide enough evidence that accretion induced dispersion in $T_\text{eff}$ and metallicity of stars could match the width of eMSTOs found in nearby open clusters.

3.2.3. Evolution of the intra-cluster metallicity spread

As mentioned above, our scenario also predicts a systematic variation of metallicity across the MSTO of a cluster. Figure 4 illustrates the metallicity effect against the cluster age. Clearly, the MSTO stars in very young clusters, aged $<200$ Myr ($M_\text{TO} > 3 M_\odot$), are most affected by accretion, as illustrated by shaded areas in these figures. These stars fully lack convective envelopes and, hence, may inherit either a completely metal-dominated atmosphere (Fig. 4, top panel) or a pure hydrogen-helium atmosphere (Fig. 4, bottom panel).

Generally, the longer the lifetime of the disc, the more prominent the effect. For example, in the case of accretion lasting 3 Myr, also older clusters, with ages of up to 500 Myr ($M_\text{TO} \sim 2.5 M_\odot$), start to exhibit this effect. Also, the initial metallicity of the stars in the cluster, $Z_\text{ini}$, plays a role, especially
in the case of metal-poor accretion. So, for example, for Z_{ini} of 0.02, the stellar atmosphere quickly becomes rich in H and He, compared to its original chemical composition and this depletion of metals, on the order of $\sim$0.005, is seen for all clusters regardless of their age. In contrast, in the case of Z_{ini} of 0.025, only the most massive stars $>3.3 M_\odot$, which can only be found in very young clusters, show a signature of metal depletion in their atmospheres. This is due to the fact that the convective envelopes of metal-poor stars recede more rapidly than the envelopes of stars of higher initial metallicity. Therefore, their envelopes are smaller at the time of accretion and the change in their surface metallicity is more prominent.

The metallicity gradient across the cluster MSTO is a very strong test of our scenario. However, notwithstanding major progress in observational studies of open clusters (e.g. the Gaia-ESO survey), there are still major limitations that make it impossible for us to use the observed samples to test our models. The main problem is that cluster membership is often based not only on stellar kinematics, but also on the metallicity of stars (e.g. Blanco-Cuaresma et al. 2015; Blanco-Cuaresma & Fraix-Burnet 2018); so the samples will be, by construction, devoid of objects with metallicities deviating from the average value of the cluster. Secondly, the interesting nearby clusters lack a thorough spectroscopic analysis. Liu et al. (2016) and D’Orazi et al. (2020) confirm the chemical inhomogeneity of Hyades and Praesepe, but their results are based on only a few MS-stars and they cannot be used as a statistically significant sample. Takeda et al. (2013) explored chemical composition of 68 stars in Hyades. Casamiquela et al. (2020) derived LTE abundances for 22 elements for 62 Hyades and 22 Praesepe stars. However, both of these studies are limited to F–G type stars and do not probe the TO of the clusters. More distant open clusters in the interesting regime of ages and metallicities have only been studied with photometry (Marino et al. 2018a; Cordoni et al. 2018). Magrini et al. (2014) provide abundances for clusters Trumpler 20, NGC 4815, and NGC 6705, but their sample only contains 21, 13, and 5 members, respectively. Finally, older clusters (such as globular cluster systems or old open clusters) have been extensively studied by means of high-resolution spectroscopy (e.g. Gruyters et al. 2014, 2016; Gao et al. 2018; Koval ev et al. 2019), however, our model suggests that the accretion induced scatter will be very small because of their high age and the resulting deep convective envelopes of their TO members.

3.2.4. Detailed stellar evolution with accretion

In our attempt to place stars with an altered surface composition on a colour-magnitude diagram, we used stellar structure models with a uniform composition, albeit modified by accretion. We assumed that the evolution and surface parameters of a star – its colour and magnitudes – only depend on the chemical composition of its outermost layers and its age. This was done for the sake of time and resources because the self-consistent evolution of stellar structure that takes surface accretion into account is computationally very expensive. However, the validity of this assumption has to be checked.

To explore the influence of heterogeneous composition on stellar evolution, we compared evolution models of stars with a uniform composition to evolution with heterogeneous composition computed using the LPCODE (Althaus et al. 2010; Renedo et al. 2010; Salaris et al. 2013). We tested how the physical parameters of a Z = 0.02 star react to doubling or halving the metallicity of its 3% upper mass. As expected, the chemical composition at the surface adjusts the effective temperature of the star, but its absolute magnitude and its lifetime are not affected. The effective temperature is modified by $\sim$300 K for stars of 1.5 $M_\odot$ and by $\sim$500 K for 3 $M_\odot$ relative to the model with a uniform chemical composition. Although this change is slightly smaller compared to the predictions of our simple model, the test confirms that random changes in surface metallicity caused by accretion from PP discs might be responsible for eMSTOs in open clusters.

4. Conclusions

In this work, we explore whether accretion of material from the protoplanetary disc can lead to significant changes in the surface physical parameters (metallicity and $T_{eff}$) of the central star with respect to its initial chemical abundance pattern set at birth.

We employed the Two-Pop-Py (TPP) code (Birnstiel et al. 2011) to model the evolution of the disc and the Garstec code (Weiss & Schlattl 2008) to model stellar evolution. We assumed instantaneous accretion and mixing throughout the stellar convective envelope and neglected perturbations of the mechanical structure of a star. We find that the accretion histories derived with the TPP code are extremely diverse, both in terms of the mass accretion rate and the dust-to-gas ratio in the accreted matter. Even within the conservative limits on the key disc parameters, the turbulent viscosity parameter, $\alpha$, and the fragmentation velocity, $v_{frac}$, the central star may undergo either a
fast early accretion of (metal-rich) dust, a slow extended accretion of (metal-poor) gas, or some combination thereof. However, the accretion of material onto the star evolves on similar timescales as the evolution of stellar structure. This result demands accretion to have an influence on the structural evolution of the star and vice versa. We encapsulate the entire range of plausible accretion scenarios by assuming two limiting cases, the metal-free and the metal-rich accretion, which are used in the simulations reported in this work.

First, we apply our method to the evolution of the Sun. We find that although the accretion potentially affects the solar surface metallicity, the effect is not substantial. Starting from the old solar composition by Grevesse & Sauval (1998), \( Z = 0.018 \), which we assume to be representative of the proto-Sun, we obtain \( Z = 0.01627 \) and \( Z = 0.02004 \) for the metal-poor and metal-rich accretion scenarios, respectively. The value reported by Caffau et al. (2011), \( Z = 0.0153 \), is consistent with our lower estimate within the uncertainty of the data, but we cannot explain the value of \( Z = 0.0134 \) reported by Asplund et al. (2009). This suggests that the influence of accretion of metal-poor material from the protoplanetary disc onto the Sun cannot be ruled out.

The effect of PP disc accretion is, however, far more important for stars more massive than the Sun. The evolution of high-mass stars, \( M > 2 M_{\odot} \), in particular, is characterised by very rapidly receding convective envelopes. During the first few million years of stellar evolution, the stars almost entirely lose their envelopes. Hence, the accretion of matter on timescales typical of the PP disc lifetimes may significantly change the mass and surface metallicity of a star. The addition of matter and readjustment of the chemical composition in the convective envelope which in return leads to changes in the evolutionary track of a star and, consequently, in the position of a star in the plane of observables (the colour-magnitude or \( T_{\text{eff}} \) vs. \( M_{\text{G}} \) – absolute magnitude diagrams). Our detailed calculations demonstrate that stars that have experienced metal-poor accretion move to the left, towards hotter \( T_{\text{eff}} \) and become more luminous. On the other hand, metal-rich accretion shifts a star to the right, towards cooler \( T_{\text{eff}} \) and lower luminosities. The effect ultimately depends on the initial metallicity and mass of a star, as well as the lifetime of the protoplanetary disc, but it would usually go unnoticed in composite stellar population or in a random sample of stars in a galaxy because they represent a mixture of objects with different ages, metallicities, and accretion histories.

The effect of accretion can be best seen in the evolution of a coeval stellar population, such as an open cluster. Our detailed calculations show that the metal-rich and metal-poor accretion scenarios lead to a characteristic broadening of the cluster main-sequence (Fig. 5). Given the stochastic nature of the disc formation problem, that is, the fact that different stars in a cluster will experience different accretion histories, it is natural to expect a dispersion of stars around some representative locus, which is canonically characterised by a “best-fit” isochrone. This dispersion is the key parameter that defines the properties of the disc accretion histories for individual stars in the cluster; it is largest at the main-sequence turn-off and it increases with decreasing the age of a cluster. Also, protracted accretion histories owing to, for example, longer disc lifetimes, may further increase the MSTO spread.

Remarkably, our model predictions for the MSTO dispersion appear to be in line with the observations of eMSTOs in open clusters of the Milky Way. To test the model, we employed six nearby Gaia DR2 clusters, which are well-populated on the MSTO and have robust measurements of kinematics, distance, and magnitudes for the individual members. The uncertainties of the data are extremely small, which rules out erroneous measurements as a viable explanation for the spread in the cluster CMD. Indeed, all of these clusters do not only show the MSTO dispersion, but they also conform to the MSTO dispersion predicted by our simple coupled accretion – stellar evolution model. Younger clusters – Blanco 1, α Per, and Pleiades – have very extended MSTOs, with dispersions exceeding 1000 K. They are consistent with our model predictions for a disc with the lifetime of, at least, 3 Myr. It is also interesting to note that clusters older than ~600 Myr – Coma Ber, Praesepe, Hyades – appear to have even larger MSTO spreads than expected from our model for their age. This may signify longer-lived discs.

In either case, precise astrometric and photometric observations by Gaia DR2 seem to support the scenario in which stars undergo a substantial change in their evolutionary tracks owing to the accretion from their natal protoplanetary discs. This intriguing signature can furthermore be explored with expanded samples of clusters with precision photometry, but also with detailed metallicity measurements of the cluster members. In particular, our model predicts a systematic variation of metallicity across the TO of a cluster. Stars that experienced the accretion of metal-poor material (gas) from their discs are shifted to the left, towards bluer colours (or higher \( T_{\text{eff}} \)), whereas the objects that underwent the accretion of metal-rich material are displaced to the right, towards redder colours (or lower \( T_{\text{eff}} \)). This peculiar effect, hence, might offer an indirect way to constrain the accretion histories and properties of protoplanetary discs of stars.
