Laughlin liquid - Wigner solid transition
at high density in wide quantum wells

Abstract

Assuming that the phase transition between the Wigner solid and the Laughlin liquid is first-order, we compare ground-state energies to find features of the phase diagram at fixed $\nu$. Rather than use the Coulomb interaction, we calculate the effective interaction in a square quantum well, and fit the results to a model interaction with length parameter $\lambda$ roughly proportional to the width of the well. We find a transition to the Wigner solid phase at high density in very wide wells, driven by the softening of the interaction at short distances, as well as the more well-known transition to the Wigner solid at low density, driven by Landau-level mixing.
In the past few years, experiments with 2-dimensional electron systems in a perpendicular magnetic field have shown a long-expected behavior as the strength of the field increases. At comparatively low fields, the now-familiar fractional quantum Hall effect appears, as the longitudinal resistivity $\rho_{xx}$ falls exponentially to zero as the temperature $T \to 0$ at fractional filling factors $\nu$. As the field increases, however, an insulating state appears, with $\rho_{xx} \to \infty$ when $T \to 0$. Optical experiments show a new spectral line developing at the same fields. This behavior is commonly thought to signal the presence of a Wigner solid, predicted many years ago, and pieces of an experimentally-derived phase diagram between the Wigner solid and the fractional quantum Hall (FQHE) or Laughlin liquid can be sketched out.

There are several experimental parameters that affect the boundary between Wigner solid and FQHE liquid. The most important is the magnetic filling factor $\nu = 2\pi n\ell^2$, where $n$ is the electron density and the magnetic length $\ell = (\hbar c/eB)^{1/2}$. The FQHE appears only at certain fractional filling factors $\nu = p/q$, where $p, q$ are integers and $q$ is odd. The Wigner solid exhibits no such detailed dependence on $\nu$, but becomes gradually more favorable as the particles are localized with decreasing $\nu$. Also important is the electron density $n$, parameterized by the ion-disk radius $r_s = (\pi n)^{-1/2}$. (Here we use atomic units, where length is measured in units of the Bohr radius $a_B = \hbar^2/me$ and energy in units of $e^2/a_B$.) As the Landau-level separation is $\hbar \omega_c = 2/\nu r_s^2$, the energy cost of localizing the particles by Landau-level mixing falls rapidly with increasing $r_s$ at fixed $\nu$, until at some critical $r_s$ the Wigner solid becomes more favorable than the FQHE liquid and the system freezes.

Finally, the experiments are all done in real systems, which must be considered quasi-two-dimensional, with some finite thickness $L$ characterizing the width of the electron layer. On average a pair of electrons is separated in the $z$-direction by $\lambda < L$, so their effective interaction at distances $r \ll \lambda$ in the $xy$ plane becomes much softer than the Coulomb interaction, while at large distances $r \gg \lambda$, the interaction is essentially Coulombic. This preserves the long-range character of the interaction while weakening the short-range part. Because the formation of the Wigner solid is driven by the long-range part of the interaction, while the FQHE liquid derives its energy advantage from the short-range part, the quasi-
two-dimensional character of a real experimental system might be expected to favor the solid somewhat. There have been several recent experiments and theoretical studies \[10,11\] of finite thickness effects on the incompressible FQHE state and, in general, it is now well-established that finite layer thickness tends to destroy incompressibility by reducing the short-range part of the Coulomb interaction. To the best of our knowledge, however, the enhancement of the Wigner solid phase by the finite thickness effect has not been examined theoretically.

In this paper, we study the quantitative effects of the three length scales \(\ell, r_s,\) and particularly \(\lambda\) on the Laughlin liquid - Wigner solid phase diagram. We compare ground-state energies and excited states of variational wavefunctions for the Wigner solid and the FQHE liquid as both \(r_s\) and \(\lambda\) are allowed to vary. We find that at small \(\lambda\), such as that found in GaAs heterojunctions, the zero-temperature phase transition from liquid to solid at large \(r_s\) does not vary much from the Coulomb case. At large \(\lambda\) we find that the FQHE liquid gives way to the Wigner solid at low density, as expected, but most unexpectedly, we find that the Wigner solid phase dominates the FQHE liquid at high density as well. Only in an intermediate range of \(r_s\) does the liquid have lower energy than the solid when \(\lambda\) is large. The interplay among the length scales \(\ell, r_s,\) and \(\lambda\) can, in principle, therefore lead to a reentrant Wigner solid transition at large \(\lambda\) as \(r_s\) is varied.

The electrons in a quantum well are confined to a small number of subbands, usually just one, and then can be thought of as extended rod-like charges in the \(z\)-direction which are allowed to move only in the \(xy\) plane. \[12\] This approximation has been used in the past to study the weakening and eventual collapse of the FQHE state in a wide quantum well. The interaction between these model charges is given by

\[
V_{\text{eff}} = \int dz_1 \int dz_2 \frac{1}{[r^2 + (z_1 - z_2)^2]^{1/2}} |\zeta(z_1)|^2 |\zeta(z_2)|^2.
\]  

(1)

Here \(\zeta(z)\) is the envelope wavefunction describing quantization in the \(z\)-direction and \(r\) is the separation between electrons in the \(xy\) plane.

The confining potential in the \(z\)-direction enters into this equation only through the
envelope wavefunction $\zeta(z)$. This wavefunction should be obtained in a self-consistent procedure which takes into account the interaction of the electrons in the $xy$ plane. At low electron density, in quantum wells where the subband splitting is large, $\zeta(z)$ is simply the $z$-component of the single-particle wavefunction. When electron density becomes higher, or the well is made wider bringing the subbands closer together, $\zeta(z)$ will be modified.

In a square well, however, $\lambda$ and $r_s$ are (roughly speaking) independent parameters, as the width of the well $L$ is to lowest order independent of the density of the electrons in the $xy$ plane. It is only when subband mixing begins to become important that the electron density begins to affect the envelope wavefunctions $\zeta(z)$. We expect that when only the lowest subband is occupied the single-particle wavefunctions will be adequate for $\zeta(z)$. The usual cosine solution for an infinite well is shown in the inset to Figure 1, as well as a gaussian wavefunction

$$\zeta_{\text{sq}}(z) = \frac{1}{(\pi \gamma^2)^{1/4}} e^{-z^2/2\gamma^2}, \quad (2)$$

fitted to the cosine solution. Here $\gamma = 0.277L$ gives the gaussian wavefunction shown in Figure 1. The effective potential for the two wavefunctions is almost identical. The gaussian wavefunction gives

$$V^{\text{sq}}_{\text{eff}}(r) = \frac{1}{\sqrt{2\pi \gamma}} e^{r^2/4\gamma^2} K_0 \left( \frac{r^2}{4\gamma^2} \right), \quad (3)$$

where $K_0$ is a modified Bessel function. We would like to use the simpler model interaction of Zhang and Das Sarma, \cite{13}

$$V_0(r) = \frac{1}{\sqrt{r^2 + \lambda^2}}, \quad (4)$$

so we choose the parameter $\lambda$ to fit $V^{\text{sq}}_{\text{eff}}(r)$ best when $r$ is large. A least-squares fit, shown in Figure 1, yields $\lambda/L = 0.2$.

Because $\lambda/L$ is small for the square well, we need a wide well if we are to investigate a system with reasonably large $\lambda$. For example, a well with $\lambda = 1$ in an electron system in GaAs is approximately 500Åwide. In these wide wells, subband mixing can become important,
and the envelope wavefunctions will tend to spread out toward the edges of the well as the electrons reduce their potential energy. We have used the self-consistent approach taken in [10] to estimate the density distribution $n(z)$, and we find that $\lambda/L$ will vary anywhere from 0.15 to 0.30 in the presence of subband mixing. [14] If we choose the lowest subband value $\lambda = 0.2L$ for the square well, $V_0(r)$ is nearly identical to $V_{\text{eff}}^{sq}(r)$ for $r \geq 0.2L$, and differs significantly from $V_{\text{eff}}^{sq}(r)$ only for $r \leq 0.1L$. The pair correlation function for both liquid and solid is small below about $r = r_s$, so we believe $V_0(r)$ to be a good description of $V_{\text{eff}}^{sq}(r)$ for $\lambda \leq 2$.

In extremely wide quantum wells, $n(z)$ will be modified further as it peaks near the well edges. The well then begins to resemble a highly-coupled double-layer system. Electrons in the well may lower their potential energy by localizing near the edges of the well, at the cost of some kinetic energy. In this more complicated situation, the approximation (1) begins to break down. At high density, the interaction between electrons that are adjacent in the $xy$-plane becomes small, as they become separated in the $z$-direction. The interaction between electrons localized on the same side of the well becomes stronger, however, and the net effect is a small potential energy savings. We should note, however, that the magnetic field will tend to suppress subband mixing, as at $\nu = 1/3$ the filling in the lowest subband will be at most $1/3$.

In this paper, we determine the zero-temperature phase boundary between Wigner solid and Laughlin liquid by comparing ground-state energies of variational wavefunctions for the liquid and the solid. Because we are simply comparing energies, we are assuming that the phase transition is first-order, and we neglect the possible presence of any other states in the vicinity. At high electron density we regard the approximation (1) as a qualitative guide only, and do not attempt to predict a critical $r_s$ and $\lambda$ quantitatively for the low $r_s$ transition.

A variational wavefunction for the liquid which interpolates in some sense between a wavefunction with the lowest possible kinetic energy, the Laughlin wavefunction, and a wavefunction with the lowest possible potential energy, in which the electrons are completely
localized, might be expected to be a good variational choice. To that end, we have chosen a variational wavefunction that consists of the Laughlin wavefunction \( \psi_m (m = 1/\nu) \) multiplied by a Jastrow factor \( \prod_{i<j} e^{-\alpha/\sqrt{r_{ij}}} \), where \( r_{ij} \) is the distance between the \( i \)th and \( j \)th particles and \( \alpha \) is the variational parameter. When \( \alpha = 0 \), we recover the Laughlin wavefunction, and when \( \alpha \neq 0 \), the wavefunction is no longer analytic and higher Landau levels are mixed in. The Jastrow factor introduces more correlations into the wave function, lowering the potential energy, while introducing a kinetic energy cost.

Details of the calculation are given in Ref.8, so we will only review it briefly here. (Note that [8] uses units of energy \( e^2/2a_B \), while this paper uses atomic units \( e^2/a_B \).) We use the spherical geometry, in which our wavefunction becomes

\[
\psi_{\alpha m} = \prod_{i<j} (u_i v_j - u_j v_i)^m \exp \left( \frac{-\alpha}{|u_i v_j - u_j v_i|^{1/2}} \right),
\]  

(5)

where \( u_i \equiv e^{-i\phi_i/2} \cos(\theta_i/2) \), \( v_i \equiv e^{i\phi_i/2} \sin(\theta_i/2) \) are convenient spinor coordinates, and the distance between particles \( i \) and \( j \) is taken as the chord distance \( r_{ij} = 2R|u_i v_j - u_j v_i| \).

Evaluating the energy of this wavefunction by Monte Carlo and minimizing at a fixed \( r_s \) and \( \lambda \) gives the results shown by the dashed lines in Figures 2 and 3.

In order to find the liquid-solid phase boundary we need a rather accurate evaluation of the solid. Lam and Girvin [6] evaluated the energy of a correlated Wigner solid wavefunction

\[
\Psi = \exp \left( \frac{1}{4} \sum_{i,j} \xi_i B_{ij} \xi_j \right) \prod_i \phi_{R_i}(z_i),
\]  

(6)

where \( \xi_i = z_i - R_i \), \( B_{ij} \equiv B(R_i - R_j) \), and

\[
\phi_{R_i}(z_i) = \exp \left( -\frac{1}{4} \left[ |z_i - R_i|^2 - (z_i^* R_i - z_i R_i^*) \right] \right).
\]  

(7)

Here \( z_i = x_i + i y_i \) is the \( i \)th particle position and \( R_i = X_i + i Y_i \) is the \( i \)th lattice site. \( \Psi \) is the harmonic crystal wavefunction restricted to the lowest Landau level, and the variational parameters \( B_{ij} \) are calculated by using the values derived from the harmonic crystal. However, in order to make a reasonable comparison of solid and liquid wavefunctions, we need, as discussed above, a wavefunction which includes Landau-level mixing.
A study of the ground-state energy of the Wigner crystal including Landau-level mixing, has recently been completed, using the Coulomb interaction. We have extended their work to use the modified potential (9). This calculation is similar to Lam and Girvin’s, except that two more variational parameters \( \alpha \) and \( \beta \) are added to the wavefunction to put in more correlations at the expense of some Landau-level mixing. First, the gaussians in the single-particle wavefunctions (7) were “squeezed” to move the electrons farther away from each other, by making the replacement
\[
\exp \left( -\frac{1}{4} |z_i - R_i|^2 \right) \rightarrow \exp \left( -\beta |z_i - R_i|^2 \right).
\]
Varying the parameter \( \beta \) away from 1/4 introduces Landau-level mixing into the wavefunction because the single-particle wavefunctions \( \phi_{R_i}^\beta(z_i) \) are no longer eigenstates of the single-particle Hamiltonian. An additional Jastrow factor is then introduced, and the final wavefunction, with two variational parameters \( \alpha \) and \( \beta \), is then
\[
\Psi = \exp \left( \sum_{i,j} \left[ \frac{1}{4} \xi_i \xi_j B_{ij} \right] - \frac{\alpha}{2} u(|z_i - z_j|) \right) \prod_i \phi_{R_i}^\beta(z_i),
\]
where
\[
u(r) = \frac{1}{\sqrt{r}} \left( 1 - e^{-\sqrt{r/F} - r/2F} \right),
\]
and \( F \) is a constant chosen to optimize the pseudo-potential at small \( r \). Zhu and Louie varied \( B_{ij} \) as well as \( \beta \), but found that varying \( B_{ij} \) had very little effect on the energy, as Lam and Girvin had suggested. The quantum Monte Carlo calculations were done with modified periodic boundary conditions, which require the addition of a phase factor to the single-particle wavefunctions. The results are shown as the solid lines in Figure 2 and the triangular data points in Figure 3.

The \( r_s = 2 \) curves in Figure 2 are very nearly the lowest Landau-level energies, since \( h \omega_c \) is large at \( r_s = 2 \). In fact, if each of the curves in Figure 2 were plotted as a function of \( \lambda/r_s \) and there were no Landau-level mixing, they would lie on top of each other. Only the increased Landau-level mixing at \( r_s = 10 \) and 20 reduces the energy there somewhat. The
parameter $\lambda/r_s$ can be thought of as the ratio of the average separation in the $z$-direction $\lambda$ and the average separation in the $xy$ plane $r_s$ (actually $\sim 2r_s$) of two nearby electrons. The lowest Landau level energies cross at $\lambda = 6$ at $r_s = 10$ and $\lambda = 12$ at $r_s = 20$, but the variational energies here predict a freezing transition at $\lambda \approx 4$ at $r_s = 10$ and possibly $\lambda \approx 6 - 7$ at $r_s = 20$. These results illustrate the fact that Landau-level mixing does in general tend to favor the solid somewhat.

The variational wavefunctions use the fact that localizing the electrons by mixing in higher Landau levels will keep nearest-neighbor electrons farther apart, and since the Coulomb potential rises rapidly at small $r$ the energy savings can be significant. As the interaction softens, however, the energy savings becomes small, and as a result the liquid and solid energies at $r_s = 2$ are nearly identical to the lowest Landau level energies. Ortiz, Ceperley, and Martin [15] have recently used their fixed-phase quantum Monte Carlo method to improve the liquid energy shown here somewhat. The difference in energy is significant at $r_s = 10$ and 20, but at $r_s = 2$ the change in energy for the Coulomb interaction is only $\sim 0.006$, a shift on the order of 10%.

The rapid descent of the solid energy with $\lambda$ leads to a freezing transition at about $\lambda = 1.2$ at $r_s = 2$, brought on by the softening of the short-range part of the interaction. Keeping the well width constant and lowering the density gives a smaller $\lambda/r_s$, and the system melts once again until the increased Landau-level mixing at high $r_s$ causes the system to freeze again. Figure 3 shows the energies of solid and liquid when $\lambda$ is fixed and $r_s$ is allowed to vary. At $\lambda = 0.5$ we find no significant lowering of the solid energy at low $r_s$, but at $\lambda = 1$ the solid energy at $r_s = 2$ is nearly as low as the liquid energy, and at $\lambda = 2$ and 3 the solid energy at $r_s = 2$ is much lower than the liquid energy. In all cases the liquid becomes favorable at lower density until Landau-level mixing again causes the system to freeze. The transition at high density has been seen in the experiment of Suen et al. [10], where an insulating phase was observed in an 800Åwell at $\nu = 1/3$, $r_s = 1.7$, which became a well-defined FQHE state when the density was lowered to $r_s = 2.2$.

We can contrast the wide well (i.e. large $\lambda$) situation, which we have argued in this
paper may be favorable to the solid phase both at large and smaller $r_s$, with the situation of a heterojunction with a metal gate which screens the inter-electron Coulomb interaction, changing it to $V_{\text{eff}}(r \to \infty) \sim 1/r^3$ and $V_{\text{eff}}(r \to 0) \sim 1/r$. For the gated heterojunction case clearly the Laughlin liquid will be preferred because the effective interaction remains Coulombic for small $r$. Thus, careful experiments in wide wells contrasted with those in gated heterojunctions would go a long way in establishing the liquid-solid phase boundary in strong-field 2D systems.
