Received date / Accepted date

Abstract. Results are presented for our search for warm-hot gas towards the quasar Q 0329 − 385. We identify ten O\textsc{iv} systems of which two are within 5000 km s\(^{-1}\) of \( z_{\text{em}} \), and a third one should be of intrinsic origin. The seven remaining systems have H\textsc{i} column densities \( 10^{13.7} \leq N(\text{H}^{}) \leq 10^{15.6} \text{ cm}^{-2} \). At least \(~1/3\) of the individual O\textsc{iv} sub-systems have temperatures \( T < 1 \times 10^{5} \text{ K} \) and cannot originate in collisionally ionized gas. Photoionization by a hard UV background field reproduces well the ionic ratios for metallicities in the range \( 10^{-2.5} - 10^{-0.5} \text{ solar} \), with possibly sub-solar N/C relative abundance. For \([\text{O}/\text{C}]=0\), the sizes inferred for the O\textsc{iv} clouds are in some cases larger than the maximum extent implied by the Hubble flow. This constraint is fulfilled assuming a moderate overabundance of oxygen relative to carbon. For a soft UV ionizing spectrum, an overabundance of O/C is required, \([\text{O}/\text{C}]=0.0-1.3\). For a hard (soft) UV spectrum and \([\text{O}/\text{C}]=0(1)\), the O\textsc{iv} regions have overdensities \( \rho/\bar{\rho} \approx 10-40 \).

Key words. cosmology: observations – intergalactic medium – galaxies: halos – quasars: absorption lines

1. Introduction

Numerical simulations suggest the existence of a warm-hot phase in the intergalactic medium, \( 10^{5} < T < 10^{7} \text{ K} \), which comprises a fraction of the baryons increasing with time. This phase should be mostly driven by shocks, at least at low redshift \( z \) (Cen & Ostriker 1999; Davé et al. 2001). Possible signatures of the warm-hot intergalactic medium (WHIM) are absorptions by high ionization species such as O\textsc{v}, O\textsc{vi} and O\textsc{vii}. These absorptions are difficult to detect as they either fall in the Ly\textalpha~ forest (below the atmospheric cut-off for \( z < 1.92 \)) or in the soft X-ray range. Successful observations of the WHIM at low \( z \) were made with the FUSE, HST and Chandra satellites (e.g. Tripp et al. 2001; Savage et al. 2002; Nicastro et al. 2002).

At \( z \sim 2-2.5 \), an analysis of the O\textsc{iv}/O\textsc{v} ratio from HST stacked spectra favors a hard UV background spectrum (thus a small break at 4 Ryd) and the inferred metallicity is \([\text{O}/\text{H}] \approx -2.2 \) to -1.3 together with an enhanced oxygen abundance relative to carbon (Telfer et al. 2002). Detection of individual O\textsc{vi} absorbers has been recently reported: for systems at \( z \sim 2.5 \) with \( N(\text{H}^{}) \sim 10^{14.0} \) to \( 10^{15.0} \text{ cm}^{-2} \), the inferred metallicity is \([\text{O}/\text{H}] \approx -3 \) to -2 (Carswell et al. 2002) and for \( N(\text{H}^{}) \geq 10^{15.5} \text{ cm}^{-2} \) the metallicity is higher, \([\text{O}/\text{H}] \geq -1.5 \) (Simcoe et al. 2002). The main heating process of the high \( z \) WHIM is still unclear: the more tenuous regions of the Ly\textalpha~ forest could be ionized by a hard UV background spectrum, whereas the high column density population could be shock heated.

A systematic, large survey of quasar absorption lines at high S/N and high spectral resolution is being completed at ESO for a sample of about 20 quasars of which half are at \( z \sim 2.6 \). In this paper, we present the results of our search for O\textsc{vi} absorbers towards one quasar of the ESO large programme, Q 0329 − 385, with several unambiguous cases of narrow, strong and weak O\textsc{vi} absorptions. The observations, the selection procedure for O\textsc{vi} systems and our O\textsc{vi} sample are presented in Sect. 2. The constraints derived from the line widths are given Sect. 3. Our modelling of the O\textsc{vi} absorbers is presented in Sect. 4. The summary and conclusions are given in Sect. 5.

2. Observations and the O\textsc{vi} sample

The quasar Q 0329 − 385 (\( z_{\text{em}} = 2.423 \)) was observed at the VLT with the UVES spectrograph. The full wavelength coverage 3050-10400 Å was obtained in two settings, using dichroics, with an exposure time of 6 hr per setting. The S/N ratio is about 30 and 100 at 3300 and 5000 Å respectively. The resolution is \( b = 6.6 \text{ km s}^{-1} \). A modified version of the ESO-UVES pipeline was used, better adapted to quasar spectra. A full description of the data reduction

method will be presented in a forthcoming paper (Aracil et al. in preparation). The absorption lines were fitted by multiple Voigt profiles using the VPFIT software package (see http://www.ast.cam.ac.uk/~rfc/vpfit.html).

To identify the O\textsc{vi} systems, we used the following criteria: either the two lines of the doublet are clearly seen or, when one line of the doublet is partly blended, the presence of this line is clearly indicated by a distinct structure within the blend. In all cases, there are H\textsc{i} Lyman lines associated with the O\textsc{vi} doublets (see Table 1).

Our sample comprises ten O\textsc{vi} systems of which two within \Delta v=5000 \text{ km s}^{-1} of the quasar redshift. The redshift, number of components used in the fit and total column densities are given in Table 1. The range of N(H\textsc{i}) and N(O\textsc{vi}) covered by these systems overlap with those of the samples of Carswell et al. (2002) and Simcoe et al. (2002). The 3\sigma detection limits for individual sub-systems are typically (12, 2.0 and 1.0) \times10^{12} \text{ cm}^{-2} for O\textsc{vi}, N\textsc{v} and C\textsc{iv} respectively. When C\textsc{iv} is detected, the upper limits for N\textsc{v} are estimated using the same number of components and same b values as for the C\textsc{iv} absorptions. When neither N\textsc{v} nor C\textsc{iv} is detected, we assume b=10 \text{ km s}^{-1} and a number of components equal to those of O\textsc{vi}.

The individual sub-systems for which a detailed modelling is presented in Sect. 4 have clean O\textsc{vi} doublets with little blending which ensures a correct estimate of the b parameter. The velocity shift between the O\textsc{vi} and C\textsc{iv} doublets is always small, \leq 5.7 \text{ km s}^{-1}, and usually larger than that between the O\textsc{vi} and Lyman lines. This was already noted by Rollinde et al. (2001). The column densities and b values are presented in Table 2. The stacked velocity plots are given only for the three intervening O\textsc{vi} systems with low b parameters.

![Fig. 1. The complex systems at z=2.2488 and 2.2515. The thin line shows the best fit model only for the lines associated with the two O\textsc{vi} main clusters; there are additional components in the velocity range between these two clusters. The line blended with C\textsc{iv} at z=2.24835 is Mg\textsc{i} at z=0.76273.](image)
in Table 1, of which five are at ∆v < 5000 km s\(^{-1}\) (shaded area). Six (11) systems have line widths \( b \leq 10(14) \) km s\(^{-1}\), thus a temperature \( T \leq 1.0(2.0) \times 10^5 \) K. In the assumption of pure collisional ionization, this would imply \( 6.3 \times 10^{-8} \leq \frac{\text{O} \, \text{vi}}{\text{O} \, \text{iv}} \leq 2.1 \times 10^{-2} \) (Sutherland & Dopita 1993) and very high oxygen abundances. At \( T \approx 1.5 \) \( \times 10^5 \) K, the values of \([\text{O}/\text{H}]\) are \( \log(\text{O} \, \text{vi}/\text{H} \, \text{i}) = (5.6, 1.5, -0.7)\) respectively. For the systems and sub-systems given in Tables 1 and 2 \( \log(\text{O} \, \text{vi}/\text{H} \, \text{i}) \) is \( \geq -1.0\). Consequently, the six individual absorbers with \( T \leq 1.0 \times 10^5 \) K would have a metallicity \([\text{O}/\text{H}]\geq 4.6\), i.e. oxygen would be the more abundant element \( \log(\text{O}/\text{H}) \geq 1.5\). This clearly rules out collisional ionization for \( \text{O} \, \text{iv} \) absorbers with \( b \leq 10 \) km s\(^{-1}\).

In addition the small velocity widths constrain the size of the absorbers. At \( z \sim 2.2\), the line broadening due to the Hubble flow implies a maximum pathlength \( d_L = 80 \, b_{10} \) kpc, assuming \( H_0 = 65\) km s\(^{-1}\) Mpc\(^{-1}\), \( \Omega_M = 0.3\) and \( \Omega_L = 0.7\). In Sect. 4.2, this value is compared to the size of the ab-
The furthest away is the above mentioned, intrinsic system: the inferred sub-solar [O/N] abundance ratio is indeed consistent with the elemental abundances (enhanced nitrogen abundance relative to solar ratios) typical of most intrinsic absorbers (Hamann 1997). For four out of the other five systems with detected O VI and C IV doublets, the observed ionic ratios imply either a super-solar [O/C] abundance ratio, as also found by Telfer et al. (2002) for WHIM clouds, and/or a sub-solar [N/C] abundance ratio.

4.2. Pathlength and abundances of some individual sub-systems

For each system the ionization parameter, U, is determined from O VI/C IV adopting a HM96 spectrum and solar relative abundances (Model A; see Fig. 6 and Table 3); the pathlength is derived from the modelled physical state of the gas. For the three sub-systems with O VI/H I >0.1, one with N(H I)>1×10^{15} cm^{-2}, the inferred sizes are compatible with limits given by the Doppler parameters (see Sect. 3) for a HM96 ionizing spectrum and solar relative abundances; the temperature is T=(3.0, 3.0 and 4.8)×10^{4} K for the z=2.24835, 2.25147 and 2.31395 absorbers respectively. However, for the z=2.36385 sub-system with O VI/H I <0.1, the inferred size is a factor ∼2 larger than the maximum size due to Hubble expansion; to have l/l_{H}≤1 implies [O/C]≥0.3. A second model is then investigated assuming a HM96 spectrum and [O/C]=1.0 (Model B). The derived ionization parameters are ∼3 times lower and l≪l_{H} for all the individual sub-systems. Finally, since softer spectra imply higher U values, thus lower densities and larger path-lengths, we consider a MHR99 spectrum only together with [O/C]=1.0 (Model C). Results for Models A and C are very similar as the decrease in U due to the enhanced [O/C] relative abundance (see Sect. 4.1) is compensated by the increase in U required by the larger break at 4 Ryd in the softer spectrum. The range in metallicity of the WHIM absorbers presented in Table 3 is [C/H]∼−0.7 to −2.9.

The constraints on the SED of the background ionizing spectrum and the [O/C] relative abundance are thus linked. Even for an ionizing spectrum as hard as the HM96 one, we find that there must be some O VI clouds with a super-solar [O/C] relative abundance. Adopting the MHR99 soft spectrum implies [O/C]≈0.0 to 1.3.

Note that in the z=2.25147 absorber, a fraction of C IV could reside in the Si IV phase. Using O VI/Nv instead to derive U, with [O/N]=0 and adopting the HM96 spectrum, gives l≃1 Mpc, inconsistent with the Hubble expansion constraint. The latter is fulfilled for [O/N]≥0.7.
Table 3. Abundances and pathlength of the O\textsc{vi} absorbers

| $z$(O\textsc{vi}) | M* | [N/C] | U | H/H\textsc{i} | l(kpc) | [C/H] |

\textsuperscript{a} Model A: $\alpha=1.5$, log (He\textsc{ii} break)=0.5, [O/C]=0.0, Model B: $\alpha=1.5$, log (He\textsc{ii} break)=0.5, [O/C]=1.0, Model C: Madau et al. (1999), [O/C]=1.0

\textsuperscript{b} Hubble flow constraint: $l_H \leq 80 \, b_{10}$ kpc.

5. Summary and conclusions

A sample of ten O\textsc{vi} absorption systems at $z=2.06-2.41$ was identified in Q 0329–385. Seven systems trace the warm-hot intergalactic medium, outside the close neighbourhood of the quasar. All the detected intervening O\textsc{vi} systems have associated H\textsc{i} absorption with column densities in the range $10^{13.7}-10^{15.6}$ cm$^{-2}$. At least $\approx 1/3$ of the individual O\textsc{vi} subcomponents have low velocity dispersions, $b<10$ km s$^{-1}$, and these unambiguous cases of low temperature, $T<1\times10^5$ K, imply a radiative ionizing process for the teneous regions of the WHIM.

The observed O\textsc{vi}/H\textsc{i} and O\textsc{vi}/C\textsc{iv} ionic ratios are well reproduced by photoionization models with a hard (HM96) spectrum and [O/C]=0, whereas the weakness or non detection of N\textsc{v} implies [O/N]>0 in most cases. The range in metallicity for our small sample is large, [C/H]$\approx -0.5$ to $-2.5$, which strongly suggests a non-uniform enrichment of the intergalactic medium. The size inferred for low $b$ absorbers of smaller O\textsc{vi}/H\textsc{i} ratios are about twice as large as that inferred from the Hubble flow constraint. For these absorbers, higher gas densities, thus sizes compatible with the Hubble flow, are obtained for [O/C]$\sim 0.3$.

An enhanced oxygen abundance is nearly always required for a softer spectrum (i.e. a larger break at 4 ryd), with [O/C]$\approx 0.0-1.3$, and the enrichment of the WHIM should then comes predominantly from massive stars. Adopting the MHR99 spectrum and [O/C]=1 leads to a metallicity range [C/H]$\approx -1.2$ to $-3.0$.

The $N$(H\textsc{i}) range of the O\textsc{vi} systems in Q 0329–385 is similar to that of the O\textsc{vi} sample of Carswell et al. (2002) and these authors also favor photoionization of the WHIM. They rule out a soft UV flux for a solar [O/C] abundance ratio, as also found for most of the O\textsc{vi} systems in Q 0329–385 but, as discussed in Sect. 4.2, a softer UV flux is acceptable if [O/C] is super-solar. On the contrary, Simcoe et al. (2002) favor shock-heated gas. However, their O\textsc{vi} survey does not trace regions of lower column densities (no system with $N$(H\textsc{i})$<1\times10^{14.5}$ cm$^{-2}$) and five out of their 12 intervening O\textsc{vi} absorbers have very large $N$(H\textsc{i}) ($10^{16.9}$ to $10^{19.5}$ cm$^{-2}$). The O\textsc{vi} systems with stronger H\textsc{i} absorption may trace the outer parts of high z galactic halos where the effects of galactic winds may dominate the heating process (Theuns et al. 2002), one of the models also suggested by Simcoe et al. (2002).

For a hard UV spectrum and [O/C]=0, the gas density is in the range $n_H=(7-23)\times10^{-5}$ cm$^{-3}$, thus O\textsc{vi} arises in regions with overdensities $\rho/\rho_\odot=10-40$ for $\Omega_\Lambda h^2_{100}=0.02$ (O‘Meara et al. 2001). Adopting a MHR99 soft spectrum and [O/C]=1 leads to the same range of overdensities, whereas for the HM96 spectrum and [O/C]=1 the overdensities are about three times larger.

We are currently building a large O\textsc{vi} sample from the dataset of the VLT-UVES quasar large programme to investigate the physical state and chemical evolution of the O\textsc{vi} absorber populations, as well as the relative occurrence of O\textsc{vi} and C\textsc{iv} systems.
