It is often argued that the principal ambiguity in fixed-order perturbative QCD calculations lies in the choice of the renormalization scale. In this paper we present a general discussion of the constraints of the renormalization group (RG) invariance on the choice of the renormalization scale. We adopt the extended RG equations for a general exposition of RG invariance, since they simultaneously express the invariance of physical observables under both the variation of the renormalization scale and the renormalization scheme parameters. We then discuss the self-consistency requirements of the RG, such as reflexivity, symmetry, and transitivity, which must be satisfied by the scale-setting method. In particular, we show that the Principle of Minimal Sensitivity (PMS) does not satisfy these requirements. The PMS requires the slope of the approximant of an observable to vanish at the renormalization point. This criterion provides a scheme-independent estimation, but it violates the symmetry and transitivity properties of the RG and does not reproduce the Gell-Mann-Low scale for QED observables. In contrast, the Principle of Maximum Conformality (PMC) satisfies all of the deductions of the RG invariance - reflectivity, symmetry, and transitivity. Using the PMC, all non-conformal $\beta_R$-terms ($R$ stands for an arbitrary renormalization scheme) in the perturbative expansion series are summed into the running coupling, and one obtains a unique, scale-fixed, scheme-independent prediction at any finite order. The PMC scales and the resulting finite-order PMC predictions are both to high accuracy independent of the choice of initial renormalization scale, consistent with RG invariance. The PMC thus eliminates a serious systematic scale error in pQCD predictions, greatly improving the precision of tests of the Standard Model and the sensitivity to new physics at collider and other experiments.

I. INTRODUCTION

Given the perturbative series for a physical quantity

$$\rho_n = C_0 \alpha_s^0(\mu) + \sum_{i=1}^{n} C_i(\mu) \alpha_s^{i+1}(\mu)$$

expanded to $n$-th order in the QCD strong coupling constant $\alpha_s(\mu)$, the renormalization scale $\mu$ must be specified in order to obtain a definite prediction. The common practice adopted in the literature is to simply guess a renormalization scale $\mu = Q$, keep it fixed during the calculation ($Q$ is usually assumed to be a typical momentum transfer of the process), and then vary it over an arbitrary range, e.g. $[Q/2, 2Q]$, in order to ascertain the scale-uncertainty. However there are many weak points of this conventional scale-setting method:

1. Although the infinite perturbative series $\rho_n \to \infty$ summed to all orders is renormalization-scale independent, the scale dependence from $\alpha_s(\mu)$ and

$$C_i(\mu)$$

do not exactly cancel at finite order, leading to a renormalization scale ambiguity.

2. The fixed-order estimate in the conventional procedure is also scheme dependent; i.e., different choice of renormalization scheme $R$ will lead to different theoretical estimates. This is the well-known renormalization scheme ambiguity [1–11].

3. The conventional scale choice can give unphysical results: For example, for the case of $W$-boson plus three-jet production at the hadronic colliders, taking $\mu$ to be the $W$-boson transverse energy, the conventional scale-setting method even predicts negative QCD cross-section at the next-to-leading-order (NLO) [12, 13].

4. As has been shown in Ref. [15], taking an incorrect renormalization scale underestimates the top quark forward-backward asymmetry at the Tevatron.

5. The conventional scale-setting procedure gives wrong results when applied to QED processes. It should be recalled that there is no ambiguity in setting the renormalization scale in QED. In the standard Gell-Mann-Low (GM-L) scheme, the renor-
There are uncancelled large logarithms, as well as "renormalon" terms in higher orders which diverge as $(n!)(\beta^R)^n\alpha^4_s$ [12]. The convergence of the perturbative series is thus problematic using conventional scale-setting. For certain processes such as the top-quark pair production, it is found that the total cross-section for the $(q\bar{q})$-channel, $q\bar{q} \rightarrow t + \bar{t}$, at the next-to-next-to-leading order (NNLO) is about 50% of the NLO cross-section using conventional scale-setting [19–21]. Thus, to derive a dependable perturbative estimate, one evidently needs to do even higher order calculations.

7. The conventional estimate shows a strong dependence on the choice of the renormalization scale $\mu$. It is clearly artificial to guess a renormalization scale $\mu = Q$ and to study its uncertainty by simply varying $\mu \in [Q/2, 2Q]$. Why is the scale uncertainty estimated only by varying a factor of 1/2 or 2, and not, say, 10 times $Q$? Sometimes, there are several choices for the typical momentum transfer of the process, all of which can be taken as the renormalization scale, such as the heavy-quark mass, the collision energy of the subprocess, etc. Which invariant provides the correct theoretical estimate? Using conventional scale-setting, there is no definite answer to these questions. One may argue that the correct renormalization scale for the fixed-order prediction can be decided by comparing with the experimental data, but this surely is process dependent and greatly depresses the predictive power of the pQCD theory.

Thus, in summary, the conventional scale-setting assigns an arbitrary range and an arbitrary systematic error to fixed-order pQCD predictions. In fact, as we discuss in this article, this ad hoc assignment of the range and associated systematic error is unnecessary and, in fact, can be eliminated.

One may ask: For a general fixed-order calculation, what is the correct "physical" scale or optimized scale? To our understanding, it should provide a prediction independent of the renormalization scheme and the choice of initial scale. A pictorial representation of what is the optimized renormalization scale is shown in Fig. (1), where the electron-muon elastic scattering through one-photon exchange is taken as an illustration. In the GM-L scheme, the optimized scale is $\mu_{opt}^2 = t$ which corresponds to the scale-invariant value $\alpha(t)$. As a comparison, the values of $\alpha$ at fixed-orders for different choice of $t_0 = Q^2 (i = 1, 2, 3, \cdots)$ are shown by thin-and-solid curves.

![Fig. 1: Pictorial representation of the optimized renormalization scale $\mu_{opt}$](image)

As a comparison, the values of $\alpha$ at fixed-orders for different choice of $t_0 = Q^2 (i = 1, 2, 3, \cdots)$ are shown by thin-and-solid curves in Fig. (1). A particular choice of $t_0$ using conventional scale-setting may lead to a value of $\alpha$ close to $\alpha(t)$, but this would only be a lucky guess and not the correct answer. As one includes higher-and-higher orders, the guessed scale will lead to a better estimate. In fact, when doing the perturbative calculation up to infinite order, any choice of $t_0$ will lead to the correct value $\alpha(t)$ as required by the RG invariance. However, if one chooses $t_0 = t$, the complete all-orders result is obtained from the onset.
II. EXTENDED RENORMALIZATION GROUP EQUATION AND THE RENORMALIZATION GROUP INVARIANCE

The scale dependence of the running coupling in gauge theory is controlled by the RG equation

$$\frac{\partial}{\partial \ln \mu^2} \left( \frac{\alpha_s^R(\mu)}{4\pi} \right) = -\sum_{i=0}^{\infty} \beta_i^R \left( \frac{\alpha_s^R(\mu)}{4\pi} \right)^{i+2},$$

where the superscript $R$ stands for an arbitrary renormalization scheme, such as MS scheme $^{36}$, $\overline{\text{MS}}$ scheme $^{25}$, MOM scheme $^{37}$, etc. Various terms in $\beta_i^R$, $\beta_1^R$, $\cdots$, correspond to one-loop and two-loop contributions respectively. In general, the $\{\beta_i^R\}$ are scheme-dependent and depend on the quark mass $m_f$. According to the decoupling theorem, a quark with mass $m_f \gg \mu$ can be ignored, and $m_f \ll \mu$. Then, for every renormalization scale $\mu$, one can divide the quarks into active ones with $m_f = 0$ and inactive ones that can be ignored. Within this framework, it is well-known that the first two coefficients $\beta_0^R$, $\beta_1^R$ are universal; i.e., $\beta_0^R \equiv 11 - 2n_f/3$ and $\beta_1^R \equiv 102 - 38n_f/3$ for $n_f$-active flavors. Hereafter, we simply write them as $\beta_0$ and $\beta_1$. It is noted that an analytic extension of $\alpha_s^{\overline{\text{MS}}}$ which incorporates the finite-mass quark threshold effects into the running of the coupling has been suggested in Ref. $^{38}$. However, numerically, it is found that taking finite quark mass effects into account analytically in the running, rather than using a fixed $n_f$ between thresholds, leads to effects of the order of one percent for the one-loop running coupling $^{38}$. Here we will work with the conventional $\{\beta_i^R\}$-functions.

It will be convenient to use the first two universal coefficients $\beta_0$ and $\beta_1$ to rescale the coupling constant and the scale-parameter in Eq. (4). By rescaling the coupling constant and the scale parameters as

$$a^R = \frac{\beta_1}{4\pi \beta_0} a_s^R \quad \text{and} \quad \tau_R = \frac{\beta_0}{\beta_1} \ln \mu^2,$$

one can express the RG equation (4) into a simpler canonical form

$$\frac{da^R}{d\tau_R} = -(a^R)^2 \left[ 1 + a^R + c_2^R (a^R)^2 + c_3^R (a^R)^3 + \cdots \right], \quad \text{(5)}$$

where $c_i^R = \beta_i^R \beta_0^{-1} / \beta_1^i$ for $i = 2, 3, \cdots$.

As an extension of the ordinary coupling constant, one can define a universal coupling constant $a(\tau, \{c_i\})$ to include the dependence on the scheme parameters $\{c_i\}$, which satisfies the following extended RG equations $^{35}$

$$\beta(a, \{c_i\}) = \frac{\partial a}{\partial \tau} = -a^2 \left[ 1 + a + c_2 a^2 + c_3 a^3 + \cdots \right], \quad \text{(6)}$$

$$\beta_n(a, \{c_i\}) = \frac{\partial a}{\partial c_n} = -\beta(a, \{c_i\}) \int_0^a \frac{x^{n+2} dx}{\beta^2(x, \{c_i\})}. \quad \text{(7)}$$

The scale-equation (6) can be used to evolve the universal coupling function from one scale to another. The scheme-equation (7) can be used to relate the coupling functions under different schemes by changing $\{c_i\}$. A solution of the scale-equation up to four-loop level has been given in Ref. $^{24}$, which agrees with that of the conventional RG-equation obtained in the literature, cf. Ref. $^{39}$. By comparing Eq. (6) with Eq. (4), there exists a value of $\tau = \tau_R$ for which

$$a^R(\tau_R) = a(\tau_R, \{c_i^R\}). \quad \text{(8)}$$

Footnote:

1 As argued by Grunberg $^3$, it is better to be called as the RG-improved effective coupling method. For simplicity, we retain the name as FAC as suggested by Stevenson $^5$. 
This shows that any coupling constant \( a^R(\tau_R) \) can be expressed by the universal coupling constant \( a(\tau, \{ c_i \}) \) under proper correspondence; i.e. the coupling constant \( a^R(\tau_R) \) can be treated as a special case of the universal coupling constant \( a(\tau, \{ c_i \}) \).

Grunberg has pointed out that any perturbatively calculable physical quantity can be used to define an effective coupling constant by incorporating the entire radiative corrections into its definition. This idea has later been discussed in detail by Refs. \[6, 11\]. Such an effective coupling constant can be used as a reference to define the renormalization procedure. The RG-invariance states that a physical quantity should be independent of the renormalization scale and renormalization scheme \[17, 18, 32–34\]. This shows that if the effective coupling constant \( a(\tau_R, \{ c_i^{R} \}) \) corresponds to a physical observable, it should be independent of any other scale \( \tau_S \) and any other scheme parameters \( \{ c_i^S \} \); i.e.

\[
\frac{\partial a(\tau_R, \{ c_i^{R} \})}{\partial \tau_S} \equiv 0 \quad \text{[scale invariance]}, \quad (9)
\]

\[
\frac{\partial a(\tau_R, \{ c_i^{R} \})}{\partial c_i^S} \equiv 0 \quad \text{[scheme invariance]} . \quad (10)
\]

**Demonstration:** We provide an intuitive demonstration for the RG invariance from the extended RG equations. Given two effective coupling constants \( a(\tau_R, \{ c_i^{R} \}) \) and \( a(\tau_S, \{ c_i^S \}) \) defined under two different schemes \( R \) and \( S \), one can expand \( a(\tau_R, \{ c_i^{R} \}) \) in a power series of \( a(\tau_S, \{ c_i^S \}) \) through a Taylor expansion:

\[
a(\tau_R, \{ c_i^{R} \}) = a(\tau_S + \bar{\tau}, \{ c_i^S + \bar{c}_i \})
\]

\[
= a(\tau_S, \{ c_i^S \}) + \left( \frac{\partial a}{\partial \tau} \right)_S \bar{\tau} + \sum_i \left( \frac{\partial a}{\partial c_i} \right)_S \bar{c}_i
\]

\[
+ \frac{1}{2!} \left[ \left( \frac{\partial^2 a}{\partial \tau^2} \right)_S \bar{\tau}^2 + 2 \left( \frac{\partial^2 a}{\partial \tau \partial c_i} \right)_S \bar{\tau} \bar{c}_i + \sum_{i,j} \left( \frac{\partial^2 a}{\partial c_i \partial c_j} \right)_S \bar{c}_i \bar{c}_j \right] + \frac{1}{3!} \left[ \left( \frac{\partial^3 a}{\partial \tau^3} \right)_S \bar{\tau}^3 + \ldots \right] + \ldots, (11)
\]

where \( \bar{\tau} = \tau_R - \tau_S \), \( \bar{c}_i = c_i^{R} - c_i^S \) and the subscript \( S \) next to the partial derivatives means they are evaluated at the point \( (\tau_S, \{ c_i^S \}) \).

The right-hand side of Eq. (11) can be regrouped according to the different orders of scheme-parameters \( \{ \bar{c}_i \} \). After differentiating both side of Eq. (11) over \( \tau_S \), we obtain

\[
\frac{\partial a(\tau_R, \{ c_i^{R} \})}{\partial \tau_S} = \frac{\partial^{(n+1)} a(\tau_S, \{ c_i^S \})}{\partial \tau_S^{(n+1)}} \bar{\tau}^n \frac{n!}{n!} + \sum_i \frac{\partial^{(n+1)} a(\tau_S, \{ c_i^S \})}{\partial c_i^S \partial \tau_S^{(n)}} \bar{c}_i \frac{1}{(n-1)!} + \ldots, (12)
\]

where \( n \) stands for the highest perturbative order for a fixed-order calculation. It is noted that Eq. (12) can be further simplified with the help of RG equations \[6, 11\]. If we set \( n \to \infty \), the right-hand-side of Eq. (12) tends to zero, and we obtain the scale-invariance equation (9). This shows that if \( a(\tau_R, \{ c_i^{R} \}) \) corresponds to a physical observable (corresponding to the case of \( n \to \infty \)), it will be independent of any other scale \( \tau_S \). Similarly, doing the first derivative of \( a(\tau_R, \{ c_i^{R} \}) \) with respect to the scheme-parameter \( c_i^S \), one can obtain the scheme-invariance equation (10).

In another words, if one uses a coupling constant \( a(\tau_S, \{ c_i^S \}) \) under the renormalization scheme \( S \) and with an initial renormalization scale \( \{ \tau_S \} \) to predict the value of \( a(\tau_R, \{ c_i^{R} \}) \), the RG-invariance \[9, 10\] tell us that

- if we have summed all types of \( c_i^S \)-terms (or equivalently the \( \beta_i^S \)-terms) into the coupling constant, as is the case of an infinite-order calculation, then our final prediction of \( a(\tau_R, \{ c_i^{R} \}) \) will be independent of any choice of initial scale \( \tau_S \) and renormalization-scheme \( S \).
- According to Eq. (12), for a fixed-order estimation (i.e. \( n \neq \infty \)), there is some residual initial-scale dependence. This is reasonable: as shown by Eq. (11), for a fixed-order calculation, the unknown \( \{ \beta_i^S \} \)-terms in the higher orders are necessary to cancel the scale dependence from the lower-order terms.

If we can find a proper way to sum up all the known-type of \( \{ \beta_i^S \} \)-terms into the coupling con-
stant, and at the same time suppressing the contributions from those unknown-type of $\{\beta_i^R\}$-terms effectively, such residual initial scale dependence can be greatly suppressed. The PMC has been designed for such purpose \[22\] \[24\], whose properties will be discussed in more detail in the following sections.

Using the RG scale-equation \[\phi\], the right-hand-side of the above equation can be rewritten as perturbative series of $a(\tau_S, \{\mu_i^R\})$, whose coefficient at each order is a $\{\beta_i^R\}$-series.

If one considers $N_c$ to be an analytic variable, then the scale-setting known from the non-Abelian theory $SU(N_c)$ must agree with the Abelian QED theory at $N_c \rightarrow 0$. This shows that above discussions are also suitable for QED; i.e. by taking the limit $N_c \rightarrow 0$ at fixed $\alpha = C_F \alpha_s$ with $C_F = (N_c^2 - 1)/2N_c$, we effectively return to the QED case \[4\] \[13\].

### III. SELF-CONSISTENCY REQUIREMENTS FOR A SCALE-SETTING METHOD

In principle, the correctness of a scale-setting method can be judged by experimental data. However, it has been suggested that some self-consistency requirements can shed light on the reliability of the scale-setting method \[31\], in which some initial discussions have been presented. These requirements together with their explanations are listed in the following:

1. Existence and Uniqueness of the renormalization scale $\mu$. Any scale-setting method must satisfy these two requirements.

2. Reflexivity. Given a $\alpha_s(\mu)$ specified at a renormalization scale $\mu$, we can express it in terms of itself but specified at another renormalization scale $\mu'$,

$$\alpha_s(\mu) = \alpha_s(\mu') + f_1(\mu, \mu')\alpha_s^2(\mu') + \cdots, \quad (14)$$

where $f_1(\mu, \mu') \propto \ln(\mu^2/\mu'^2)$. When the scale $\mu'$ is chosen to be $\mu$, the above equation reduces to a trivial identity.

From the scale-invariance \[\phi\], up to infinite orders, we have

$$\frac{\partial \alpha_s(\mu)}{\partial \ln \mu^2} = 0. \quad (15)$$

- If setting all the differences of the renormalization scheme parameters, $\tilde{c}_i = 0$ ($i = 1, 2, \cdots$), Eq.\[11\] returns to a scale-expansion series for the coupling constant expanding over itself but specified at another scale; i.e.

\begin{equation}
a(\tau_S, \{\mu_i^R\}) = a(\tau_S, \{\mu_i^R\}) + \left(\frac{\partial a(\tau_S, \{\mu_i^R\})}{\partial \tau_s}\right) \bar{\tau} + \frac{1}{2!} \left(\frac{\partial^2 a(\tau_S, \{\mu_i^R\})}{\partial \tau_S^2}\right) \bar{\tau}^2 + \frac{1}{3!} \left(\frac{\partial^3 a(\tau_S, \{\mu_i^R\})}{\partial \tau_S^3}\right) \bar{\tau}^3 + \cdots. \quad (13)
\end{equation}

This, inversely, means that if $\alpha_s(\mu)$ is known (say, a experimentally measured effective coupling), and we try to use the above perturbative equation to “predict” $\alpha_s(\mu)$ from itself, then any deviation of $\mu'$ from $\mu$ would lead to an inaccurate result due to the truncation of expansion series.

More explicitly, for a fixed-order expansion with the highest perturbative-order $n$, from Eq.\[12\], we obtain

\begin{equation}
\frac{\partial \alpha_s(\mu)}{\partial \ln \mu^2} \propto \left(\frac{\ln \mu^2/\mu'^2}{n!}\right)^n \frac{\partial^{(n+1)} \alpha_s(\mu)}{\partial (\ln \mu^2)^{(n+1)}} \quad (14)
\end{equation}

This shows, generally, the right-hand-side of Eq.\[14\] depends on $\mu'$ at any fixed-ordered.

Thus, to get a correct fixed-order estimate for $\alpha_s(\mu)$, a self-consistency scale-setting must take the unique value $\mu' = \mu$ on the right-hand-side of Eq.\[14\]. If a scale-setting satisfies such property, we say it is reflexive.

It is found that the Reflexivity is a basic requirement for a self-consistency scale-setting method and for the physical coupling constant $\alpha_s(\mu)$, which provides the necessary condition for the following two properties Symmetry and Transitivity; i.e. if a scale-setting does not satisfy the Reflexivity, it cannot satisfy the following two properties Symmetry and Transitivity either.

3. Symmetry. Given two different coupling constants $\alpha_{s1}(\mu_1)$ and $\alpha_{s2}(\mu_2)$ under two different renormalization schemes, we can expand any one of them in terms of the other:

$$\alpha_{s1}(\mu_1) = \alpha_{s2}(\mu_2) + \tau_{12}(\mu_1, \mu_2)\alpha_{s2}^2(\mu_2) + \cdots, \quad (10)$$

$$\alpha_{s2}(\mu_2) = \alpha_{s1}(\mu_1) + \tau_{21}(\mu_2, \mu_1)\alpha_{s1}^2(\mu_1) + \cdots. \quad (11)$$

After a general scale-setting, we have

$$\alpha_{s1}(\mu_1) = \alpha_{s2}(\mu_2^*_{1}) + \tilde{\tau}_{1}(\mu_1, \mu_2^*)\alpha_{s2}^2(\mu_2^*) + \cdots,$$

$$\alpha_{s2}(\mu_2) = \alpha_{s1}(\mu_1^*) + \tilde{\tau}_{2}(\mu_2, \mu_1^*)\alpha_{s1}^2(\mu_1^*) + \cdots.$$
4. The new effective scales $\mu_{1,2}^*$ may or may not be equal to $\mu_{1,2}$, depending on the choice of the scale-setting method. The coefficients $\tilde{r}_{12}$ and $\tilde{r}_{21}$ are changed accordingly in order to obtain a consistent result.

We have implicitly set the effective scales at NLO-level to be equal to the LO ones. We will adopt this choice throughout the paper. The effective scales for the highest-order terms are usually taken as the same effective scales at the one-lower-order, since they are the scales strictly set by the known-terms 23, 55.

Setting $\mu_2^* = \lambda_{21}\mu_1$ and $\mu_1^* = \lambda_{12}\mu_2$, if
\[
\lambda_{12}\lambda_{21} = 1,
\] (16)

we say that the scale-setting is symmetric.

Explanation:

If $\mu_2^* = \lambda_{21}\mu_1$ and $\mu_1^* = \lambda_{12}\mu_2$, we obtain
\[
\begin{align*}
\alpha_s(\mu_1) &= \alpha_s(\lambda_{12}\lambda_{21}\mu_1) + [\tilde{r}_{12}(\mu_1, \lambda_{21}\mu_1) + \tilde{r}_{21}(\lambda_{21}\mu_1, \lambda_{12}\lambda_{21}\mu_1)]\alpha_s^2(\lambda_{12}\lambda_{21}\mu_1) + \cdots. \\
\alpha_s(\mu_2) &= \alpha_s(\mu_2) + \tilde{r}_{23}(\mu_2, \mu_3)\alpha_s^2(\mu_3) + \cdots, \\
\alpha_s(\mu_3) &= \alpha_s(\mu_1) + \tilde{r}_{31}(\mu_3, \mu_1)\alpha_s^2(\mu_1) + \cdots.
\end{align*}
\] (19)

From the Reflexivity property, if a scale-setting is symmetric, i.e. satisfying Eq. (16), we obtain
\[
\tilde{r}_{12}(\mu_1, \mu_2^*) + \tilde{r}_{21}(\mu_2, \mu_1^*) = 0,
\] (20)

and vice versa. This shows that the Symmetry property (16) and the relation (20) are mutually necessary and sufficient conditions.

The Symmetry feature is necessary since it further gives us a unique relation for the scales before and after the scale-setting,
\[
\lambda_{12}\lambda_{21} = 1.
\] (21)

we say that the scale-setting is transitive.

Explanation:

If $\mu_2^* = \lambda_{21}\mu_1$, $\mu_3^* = \lambda_{32}\mu_2$ and $\mu_1^* = \lambda_{13}\mu_3$, we obtain
\[
\begin{align*}
\alpha_s(\mu_1) &= \alpha_s(\lambda_{13}\lambda_{32}\lambda_{21}\mu_1) + \alpha_s^2(\lambda_{13}\lambda_{32}\lambda_{21}\mu_1) \times \\
&\quad [\tilde{r}_{31}(\lambda_{32}\lambda_{21}\mu_1, \lambda_{13}\lambda_{32}\lambda_{21}\mu_1) + \tilde{r}_{23}(\lambda_{21}\mu_1, \lambda_{32}\lambda_{21}\mu_1) + \tilde{r}_{12}(\mu_1, \lambda_{21}\mu_1)] + \cdots. \\
\alpha_s(\mu_2) &= \alpha_s(\mu_2) + \tilde{r}_{23}(\mu_2, \mu_3)\alpha_s^2(\mu_3) + \cdots, \\
\alpha_s(\mu_3) &= \alpha_s(\mu_1) + \tilde{r}_{31}(\mu_3, \mu_1)\alpha_s^2(\mu_1) + \cdots.
\end{align*}
\] (25)

As a combination of Eqs. (23, 28, 24), we obtain
\[
\begin{align*}
\alpha_s(\mu_1) &= \alpha_s(\lambda_{13}\lambda_{32}\lambda_{21}\mu_1) + \alpha_s^2(\lambda_{13}\lambda_{32}\lambda_{21}\mu_1) \times \\
&\quad [\tilde{r}_{31}(\lambda_{32}\lambda_{21}\mu_1, \lambda_{13}\lambda_{32}\lambda_{21}\mu_1) + \tilde{r}_{23}(\lambda_{21}\mu_1, \lambda_{32}\lambda_{21}\mu_1) + \tilde{r}_{12}(\mu_1, \lambda_{21}\mu_1)] + \cdots. \\
\alpha_s(\mu_2) &= \alpha_s(\mu_2) + \tilde{r}_{23}(\mu_2, \mu_3)\alpha_s^2(\mu_3) + \cdots, \\
\alpha_s(\mu_3) &= \alpha_s(\mu_1) + \tilde{r}_{31}(\mu_3, \mu_1)\alpha_s^2(\mu_1) + \cdots.
\end{align*}
\] (26)

From the Reflexivity property, if a scale-setting is transitive, i.e. satisfying Eq. (21), we will obtain
\[
\tilde{r}_{12}(\mu_1, \mu_2^*) + \tilde{r}_{23}(\mu_2^*, \mu_3^*) + \tilde{r}_{31}(\mu_3^*, \mu_1) = 0.
\] (26)
and vice versa. This shows that the Transitivity property \(^{(21)}\) and the relation \(^{(29)}\) are mutually necessary and sufficient conditions.

The Transitivity property shows that under a proper scale-setting method, we have \(\lambda_{21} = \lambda_{32} \lambda_{12}\), which means that the scale ratio \(\lambda_{21}\) for any two couplings \(\alpha_{s1}\) and \(\alpha_{s2}\) is independent of the choice of an intermediate coupling \(\alpha_{s3}\) under any renormalization scheme. Thus the relation between any two observables is independent of the choice of renormalization scheme. In fact, the Transitivity property provides the theoretical foundation for the existence of commensurate scale relations among different physical observables \(^{(44)}\).

The Transitivity feature gives us a unique relation for all the scales before and after the scale-setting,

\[
\mu_1 \mu_2 \mu_3 = \mu_1^* \mu_2^* \mu_3^*.
\]

The Transitivity property is very important for a self-consistency scale-setting, which is a natural requirement from the RG invariance. It has already been pointed out that why the renormalization group is called a “group” is mainly because of such Transitivity property \(^{(32,34)}\).

The Transitivity property \(^{(21)}\) can be extended to an arbitrary number of coupling constants; i.e. if we have \(n\) coupling constants which are related with similar manner as above, then their transitivity relation is

\[
\lambda_{1n} \lambda_{n(n-1)} \cdots \lambda_{32} \lambda_{21} = 1.
\]

One may observe that the Symmetry is a special case of Transitivity, since if setting \(\alpha_{s3} (\mu_3) \equiv \alpha_{s1} (\mu_1)\), we have \(\lambda_{11} \equiv 1\) and \(\tilde{\tau}_{11} (\mu_1, \mu_1) \equiv 0\) due to the Reflexivity, which thus changes the transitive relation \(\lambda_{13} \lambda_{32} \lambda_{21} = 1\) into the symmetric relation \(\lambda_{12} \lambda_{21} = 1\).

As a summary, a scale-setting method that satisfies Existence and Uniqueness of the renormalization scale, Reflexivity, Symmetry, and Transitivity effectively establishes equivalent relations among all the effective coupling constants, and thus, among all the physical observables.

A. A graphic explanation of these requirements

In this subsection, we present a more intuitive explanation of these requirements based on the universal coupling \(a(\tau, \{c_i\})\) and the extended RG Eqs. \((37)\).

In the extended RG equations \((37)\), there is no explicit reference to the QCD parameters, such as the number of colors or the number of active-flavors. Therefore, aside from its infinite dimensional character, \(a(\tau, \{c_i\})\) is just a mathematical function like, say, Bessel functions or any other special functions \(^{(35)}\). In practice, due to the unknown higher order scheme parameters \(\{c_i\}\), we need to truncate the beta function \(\beta(a, \{c_i\})\) and solve the universal coupling constant \(a(\tau, \{c_i\})\) in a finite-dimensional subspace; i.e. we need to evaluate \(a(\tau, \{c_i\})\) in a subspace where higher order \(\{c_i\}\)-terms are zero. In principle, this function can be computed to arbitrary degree of precision, limited only by the truncation of the fundamental beta function.

In this formalism, any two effective coupling constants can be related by some evolution path on the hyperspace defined by \(a(\tau, \{c_i\})\). In Fig. \((2)\) we illustrate the paths which represent the operations of Reflexivity, Symmetry and Transitivity. We can pictorially visualize that the evolution paths satisfy all these three self-consistency properties. A closed path starting and ending at the same point \(A\) represents the operation of identity. Since the predicted value does not depend on the chosen path, if the effective coupling constant at \(A\) is \(a_A\), after completing the path we will also end up with an effective coupling \(a_A\). Similarly, if we evolve \(a_B\) at \(B\) to a value \(a_C\) at \(C\), we are guaranteed that when we evolve \(a_C\) at \(C\) back to the point \(B\), the result will be \(a_B\). Hence, the evolution equations also satisfy Symmetry. Transitivity follows in a similar manner; i.e. going directly from \(D\) to \(E\) gives the same result as going from \(D\) to \(E\) through a third point \(F\).

In the following two sections, we will make a detailed discussion on how these self-consistency conditions are satisfied or broken by the two frequently adopted scale-setting methods: BLM/PMC and PMS. As for FAC, its FAC scale is determined by requiring all higher order
corrections to be zero \(^2\). FAC satisfies all the above mentioned self-consistency requirements, whose demonstration is similar to that of BLM/PMC and is simpler \(^3\), so we will not repeat it here.

**IV. THE PMC SCALE-SETTING**

The PMC provides the principle underlying BLM scale-setting, so if not specially stated, we usually treat them on equal footing.

**A. What is PMC ?**

In the original BLM paper \(^{11}\), the physical observable is expanded as

\[
\rho = C_0 \alpha_{s, \overline{MS}}(\mu) \left[ 1 + (A\beta_0 + B) \frac{\alpha_{s, \overline{MS}}(\mu)}{\pi} \right],
\]

where \(\mu\) is the renormalization scale, the \(n_f\) term is due to the quark vacuum polarization. For clarity, we have taken the familiar \(\overline{MS}\)-scheme. When absorbing all the NLO terms involving \(n_f\) into the running coupling, we obtain \(^{11}\)

\[
\rho = C_0 \alpha_{s, \overline{MS}}(\mu^*) \left[ 1 + C_1^* \frac{\alpha_{s, \overline{MS}}(\mu^*)}{\pi} \right],
\]

where

\[
\mu^* = \mu \exp(3A) \quad \text{and} \quad C_1^* = \frac{33}{2} A + B.
\]

The new scale \(\mu^*\) and the coefficient \(C_1^*\) are \(n_f\) independent. The term \(33A/2\) in \(C_1^*\) serves to remove that part of the constant \(B\) which renormalizes the NLO coupling constant.

Through these procedures, it was suggested that the pQCD convergence can be greatly improved \(^{11}\). However, after a proper extension of BLM, it can do much more than that.

In deriving Eq. (29), Brodsky-Lepage-Mackenzie already observed that to derive the correct scheme-independent LO QED/QCD scale, one should deal with the \(\beta_0\)-term rather than the \(n_f\)-term. This point has lately been emphasized in Ref. \(^{45}\), where an interesting feature for the NLO BFKL Pomeron intercept function \(\omega(Q^2, 0)\) has been found; i.e. after using BLM scale-setting, the function \(\omega(Q^2, 0)\) has a very weak dependence on the gluon virtuality \(Q^2\) in comparison with that derived from the conventional scale-setting under the MOM scheme and \(\overline{MS}\) scheme \(^{45}\). The BLM has also been applied with some modifications for determining the effective scale in lattice perturbative theory by Lepage and Mackenzie \(^{46}\), which greatly enhances the predictive power of lattice perturbative theory. However, BLM in its original form is difficult to be applied to higher order calculations because of the emergence of higher order \(n_f\)-terms as \(n_f^2\)-term, \(n_f^3\)-term, etc.

Some initial ideas to deal with those higher order \(n_f\)-terms in the NNLO level can be found in Ref. \(^{44}\), which can be regarded as the rudiment of the PMC procedure, where it is observed that to deal with the \(n_f^2\)-term at the NNLO, it is better to arrange it into \(\beta_0^2\)-term and then absorb it into the coupling constant \(^3\).

The pioneering work for PMC is done in Ref. \(^{22}\), which shows that a single global PMC scale, valid at LO, can be derived from basic properties of the perturbative QCD cross-section. Later on, explicit formulae for setting PMC scales up to NNLO has been presented in Ref. \(^{23}\). It has also been pointed out that by introducing the PMC-BLM correspondence principle, we can improve the previous BLM procedure to deal with the process up to all orders, whose estimation is the same as PMC. In this sense, we say that PMC and BLM are equivalent to each other. Recently, by applying PMC to the top-quark pair hadroproduction up to NNLO level at the Tevatron and LHC colliders, the most striking feature of PMC has been observed, which shows that the PMC scales and the resulting finite-order PMC predictions are both to high accuracy independent of the choice of an initial renormalization scale, consistent with RG-invariance \(^{15}\). This implies that the serious systematic renormalization scale error introduced by using conventional scale-setting can be eliminated by PMC through a self-consistency way.

\(^2\) This method itself is useful to define an effective coupling constant for a physical process \(^4\). However it will give wrong result when applied to QED processes. The FAC forces all higher order corrections to vanish and runs the risk of the better approximation being “dragged down” by the poorer one \(^8\).

\(^3\) Strictly, together with the \(n_f\)-term at the same order, it should be arranged into a proper linear combination of \(\beta_1\)-term and \(\beta_0^2\)-term, and the \(\beta_0^2\)-term will be absorbed into LO PMC scale and \(\beta_1\)-term will be absorbed into NLO PMC scale \(^{24}\).
This prescription ensures that, as in QED, vacuum polarization contributions due to the light-fermion pairs are absorbed into the coupling constant. Note that because $C_{11} \propto \tilde{C}_{11}$, one can practically obtain the PMC scale by using the equation $C_{11}(\mu_{PMC}) = 0$, which is usually adopted in the literature. However one should keep in mind that Eq. (33) is exact.

It is noted that the $\{\beta_R^i\}$-series derived from Eq. (15) provides the foundation for the PMC-BLM correspondence principle suggested in Ref. [22], since it shows which $\{\beta_R^i\}$-terms should be kept at a specific perturbative order so as to derive a unique one-to-one correspondence with the known $n_f$-series at the same perturbative order.

B. The properties of PMC

It is straightforward to verify that PMC satisfies all the self-consistency requirements outlined above.

1. The Existence and Uniqueness of the renormalization scale $\mu$ are guaranteed, since the scale-setting conditions for PMC are often linear equations in $\ln \mu^2$.

As a simpler explanation, if the NLO coefficient $C_1(\mu)$ in Eq. (11) has the form

$$C_1(\mu) = (a + b n_f) + (c + d n_f) \ln \mu^2,$$  

with $a, b, c$ and $d$ are constants free of $n_f$. The LO PMC scale can be set as

$$\ln \mu_{POMC} = -\frac{b}{2d} + O(\alpha_s),$$

where the higher order $\alpha_s$-terms will be determined by $n_f$-terms at the NLO-level or even higher levels.

2. Reflexivity is satisfied. The PMC requires all $\ln(\mu^2/\mu'^2)$-terms in Eq. (14) vanish, thus we obtain

$$\mu' = \mu.$$  

3. Symmetry is trivial, because after PMC scale-setting, we always have

$$\tilde{r}_{12}(\mu_1, \mu_2') = -\tilde{r}_{21}(\mu_2, \mu_1').$$

---

4 In practice, we can directly deal with $n_f$-terms of the coefficients without changing them into $\{\beta_R^i\}$-terms, and eliminate the $n_f$-terms from the highest power to none also in an order-by-order manner. The results are the same due to the PMC-BLM correspondence.

5 This should be used with care, since if $C_{10}$ is a constant free of scale, then such practical way will give wrong NLO coefficient other than the correct one $C_{10}$.

6 This is the consistent way of treating the $\{\beta_R^i\}$-terms in the perturbative series. However, such a choice of $\{\beta_R^i\}$-series is different from that of Refs. [22][23], where as an extension of BLM to all orders, all possible types of $\{\beta_R^i\}$-terms which can be constructed from all the linear combination of the $n_f$-terms at the same perturbative order have been introduced to deal with the Adler D-function.
That is, the two NLO coefficients only differ by a sign. Thus, requiring one of them to be \{\beta^R_i\}-independent is equivalent to requiring the other one also to be \{\beta^R_i\}-independent. This argument ensures the symmetric relation, \(\lambda_{12}\lambda_{21} = 1\), is satisfied after PMC scale-setting.

4. Transitivity is also satisfied by PMC. After PMC scale-setting, the two coefficients \(\tilde{r}_{12}\left(\mu_1, \mu_2^*\right)\) and \(\tilde{r}_{23}\left(\mu_2^*, \mu_3^*\right)\) in the following two series
\[
\alpha_{s1}^{(\mu_1)} = \alpha_{s2}^{(\mu_2^*)} + \tilde{r}_{12}^{(\mu_1, \mu_2^*)}\alpha_{s2}^{(\mu_2^*)} + \mathcal{O}\left(\alpha_{s2}^{3}\right) \quad (36)
\]
and
\[
\alpha_{s2}^{(\mu_2^*)} = \alpha_{s3}^{(\mu_3^*)} + \tilde{r}_{23}^{(\mu_2^*, \mu_3^*)}\alpha_{s3}^{(\mu_3^*)} + \mathcal{O}\left(\alpha_{s3}^{3}\right) \quad (37)
\]
should be independent of \{\beta_i\}. After substituting Eq. (37) into Eq. (36), we obtain
\[
\alpha_{s1}^{(\mu_1)} = \alpha_{s3}^{(\mu_3^*)} + \left[\tilde{r}_{12}^{(\mu_1, \mu_2^*)} + \tilde{r}_{23}^{(\mu_2^*, \mu_3^*)}\right]\alpha_{s3}^{(\mu_3^*)} + \mathcal{O}\left(\alpha_{s3}^{3}\right) \quad (38)
\]
We see that the new NLO coefficient \[\tilde{r}_{12}^{(\mu_1, \mu_2^*)} + \tilde{r}_{23}^{(\mu_2^*, \mu_3^*)}\] will also be \{\beta^R_i\}-independent, since it is the sum of two \{\beta^R_i\}-independent quantities. These arguments ensure the transitive relation, \(\lambda_{31} = \lambda_{32}\lambda_{21}\), be satisfied after PMC scale-setting.

As a combination of all the above mentioned PMC features, the advantages of PMC are clear:

- It keeps the information of the higher order corrections but in a more convergent perturbative series. After PMC scale-setting, the divergent "renormalon" series with \(n_t\)-growth disappear, so that a more convergent perturbative series is obtained. Such better convergence has already been found in the original BLM paper [11] and the following BLM-literature even at the NLO level.
- It is renormalization-scheme independent. After PMC scale-setting:
  - The resulting expressions are conformally invariant and thus do not depend on the choice of renormalization scheme.

\[7\] In the PMC, the same procedure is valid for both space-like and time-like arguments; in particular this leads to well-behaved perturbative expansion, since all the large \{\beta^R_i\}-dependent terms on the time-like side involving \(\pi^2\)-terms are fully absorbed into the coupling. The PMC does not change the space-like or time-like nature of the initial renormalization scale \(Q_0\), since in general, all the PMC scales are equal to \(Q_0\) times an exponential factor [24].

- One can obtain proper scale-displacements among the PMC scales which are derived under different schemes or conventions.
- One can obtain commensurate scale relations (CSRs) between two physical observables such as the Generalized Crewther Relation connecting the Bjorken sum rule to the \(e^+e^-\) annihilation cross section. The CSRs have no scale ambiguity and are independent of the choice of renormalization scheme. The relative scales in the CSRs ensure that two observables pass through each quark threshold in synchrony. The coefficients in the commensurate scale relation can be identified with those obtained in conformally invariant gauge theory [47, 48].

- The PMC provides a fundamental and systematic way to set the optimized renormalization scale for the fixed-order calculation. In principle, PMC needs an initial renormalization scale to initialize it. However, it is found that the estimates after PMC scale-setting are independent of any choice of the initial renormalization scale - even the PMC scales themselves are independent of any choice of initial scale and are ‘physical’ at any fixed order. This is because that the PMC scale itself is a perturbative series and the unknown higher-order \{\beta^R_i\}-terms are to be absorbed into the higher-order term of PMC scale and will be strongly power suppressed. One example of this behavior is shown in Refs. [12, 19, 24], where the top-quark pair total cross-section and the top-quark pair forward-backward asymmetry are almost free from the choice of initial renormalization scale even at the NNLO-level.

- Moreover, it is found that the PMC scale-setting can also be adopted for QED case. The variable \(N_C\) can be taken as an analytic variable. In the Abelian limit \(N_C\to 0\) at fixed \(\alpha = C_F\alpha_s\), with \(C_F = (N_c^2 - 1)/2N_c\) and the PMC method agrees with the standard Gell Mann-Low procedure for setting the renormalization scale in QED, a consistency requirement of analyticity of Yang Mills gauge theories.

- After PMC scale-setting, the number of active flavors \(n_f\) is correctly determined [38]. Using the PMC ensures that the expansion is unchanged as one passes each quark threshold, since all vacuum-polarization effects due to each new quark are automatically absorbed into the effective coupling constant.

- The argument of the running coupling has timelike or spacelike values appropriate to the physics of the PMC scale; for example the scale of the QED coupling which some all vacuum polarization corrections in the lowest order \(e^+e^-\to \mu^+\mu^-\) amplitude
is $\alpha(t)$ in the Gell Mann-Low scheme. As in QED, the running QCD coupling is complex in the time-like domain, reflecting the contribution of diagrams with physical unitarity cuts.

V. THE PMS SCALE-SETTING

A. What is PMS?

The PMS states that [7–10] if an estimate depends on some “unphysical” parameters [8], then their values should be chosen so as to minimize the sensitivity of the estimate to small variations in these parameters; i.e. this method chooses $\mu_{PMS}$ at the stationary point of $\rho_N$:

$$\frac{\partial \rho_N}{\partial \mu} |_{\mu=\mu_{PMS}} \equiv 0$$

or

$$\frac{\partial \rho_N}{\partial \ln(\mu^2)} |_{\mu=\mu_{PMS}} \equiv 0. \quad (40)$$

Here Eq. (40) can be solved with the help of the usual renormalization group equation [4].

B. The properties of PMS

Unlike the case of PMC, in general, there are no known theorems that guarantee the Existence or the Uniqueness of the PMS solution. Although for practical cases PMS does provide solutions, and when there are more than one solution usually only one of them lies in the physically reasonable region [8–10], these observations alone do not prove that PMS will be trouble-free for new processes.

To discuss PMS properties in a renormalization scheme-independent way, following the suggestion of Ref. [31], we adopt the 't Hooft scheme [50] to define the coupling constant. Under the 't Hooft scheme, all the scheme parameters $\{c_i\}$ are set to zero, and Eq. (40) simplifies to

$$\frac{da}{d\tau} = -2^2(1 + a), \quad (41)$$

whose solution can be written as

$$\tau = \frac{1}{a} + \ln \left( \frac{a}{1 + a} \right). \quad (42)$$

In the above solution, for convenience, we have redefined $\tau$ as $\frac{a^2}{\beta_1} \ln \left( \frac{\mu^2}{\Lambda^2_{QCD}} \right)$, where $\Lambda^2_{QCD}$ is the asymptotic scale of the 't Hooft scheme. The 't Hooft coupling constant has a formal singularity, $a(\tau, \{c_i\}) \equiv a(0, \{0\}) = \infty$, which provides a precise definition for the asymptotic scale $\Lambda^2_{QCD}$ [50]; i.e. it is defined to be the pole of the coupling function.

Given two coupling constants $a_1$ and $a_2$ under the 't Hooft scheme, they are related by the perturbative series

$$a_1(\tau_1) = a_2(\tau_2) + (\tau_2 - \tau_1)a_2^2(\tau_2) + \cdots. \quad (43)$$

PMS proposes the choice of $\mu_2$ (or equivalently, $\tau_2$) at the stationary point, i.e.:

$$\frac{d a_1}{d \tau_2} = 0 = \frac{d}{d \tau_2} \left[ a_2(\tau_2) + (\tau_2 - \tau_1)a_2^2(\tau_2) \right]. \quad (44)$$

Then, we obtain the condition:

$$1 + a_2 = \frac{1}{2(\tau_1 - \tau_2)}. \quad (45)$$

In order to obtain $\tau_2$ in terms of $\tau_1$, one must solve the last equation in conjunction with

$$\frac{1}{a_2} + \log \left( \frac{a_2}{1 + a_2} \right) = \tau_2. \quad (46)$$

FIG. 4: The dependence of the PMS scale parameter $\tau_2$ as a function the external scale parameter $\tau_1$.

In Fig. 4 we present the graphical solution of the PMS scale-parameter $\tau_2$ as a function the external scale-parameter $\tau_1$. One may observe two points:

- $\tau_2 \geq \tau_1 - \frac{1}{2}$. Since $\tau_2 \neq \tau_1$ in any cases, so PMS explicitly violates the Reflexivity. For a fixed-order estimation, when one uses an effective coupling constant to predict itself, the application of PMS would lead to an inaccurate result. If PMS cannot provide the optimum scale even in this simple situation, its reliability for other processes is questionable.

- In the large momentum region ($\tau_1 \gg 1$), we obtain $a_2(\tau_2) \to 0$, and

$$\tau_2 \simeq \tau_1 - \frac{1}{2}. \quad (47)$$

$\tau_2 \equiv \tau_1 - \frac{1}{2}.$

$\tau_2 \equiv \tau_1 - \frac{1}{2}.$
Under the same renormalization scheme $R$, we have the same asymptotic parameter $\Lambda_{QCD}^{\mu H-R}$ for both $a_1$ and $a_2$. Here $\Lambda_{QCD}^{\mu H-R}$ is the 't Hooft scale associated with the $R$-scheme, where the word "associated" means we are choosing the particular 't Hooft scheme that shares the same 't Hooft scale with the $R$-scheme. Then the relation (47) in terms of $\mu_1$ and $\mu_2$ becomes

$$\mu_2 \simeq \mu_1 \exp \left(-\frac{\beta_1}{4\beta_0} \right).$$

(48)

More generally, it is found that after PMS scale-setting, the scale displacement between any two scales $\mu_i$ and $\mu_j$ in the large momentum region is

$$\lambda_{ij} = \frac{\mu_i}{\mu_j} \simeq \exp \left(-\frac{\beta_1}{4\beta_0} \right).$$

(49)

This would mean that

$$\lambda_{12} \lambda_{21} \simeq \exp \left(-\frac{\beta_1}{2\beta_0} \right) \neq 1,$$

$$\lambda_{13} \lambda_{32} \lambda_{21} \simeq \exp \left(-\frac{3\beta_1}{4\beta_2} \right) \neq 1.$$  

(50)

(51)

This shows the PMS does not satisfy the Symmetry and Transitivity requirements. When we successively express one effective charge in terms of others, PMS would lead to inconsistent scale choices. We can only conclude that the PMS method in general does not provide the optimum scale, since an optimum scale-setting method should satisfy all the self-consistency requirements listed in Sec.III.

Let us point out that adding the scheme-parameter optimization in PMS does not change any of the above conclusions. It only make the solution much more complicated [51]. The inability of PMS to meet these self-consistency requirements resides in that the derivative operations in general do not commute with the operations of Reflexivity, Symmetry and Transitivity.

As argued in Sec.III, any truncated perturbative series will explicitly break RG-invariance [9]: i.e. Eq. (9) can only be approximately satisfied for any fixed-order estimation. The precision depends on to which perturbative order we have calculated, the convergence of the perturbative series, and how we set the renormalization scale. However, the PMS does not respect this, since as shown by Eq. (10), it requires the truncated series, i.e. the approximant of a physical observable, to satisfy the RG-invariance near $\mu = \mu_{PM}$. This provides the underlying reason for why PMS does not satisfy the Reflexivity, Symmetry and Transitivity properties.

The PMC and PMS scale-setting methods each give specific predictions for physical observables at finite order; however, their predictions are very different:

- The PMC sums all $\{\beta^R\}$-terms in an arbitrary renormalization scheme $R$ in the fixed-order prediction into the running coupling, leaving the conformal series. It satisfies all of the RG-properties

**Reflexivity, Symmetry, and Transitivity.** The PMC prediction is thus scheme-independent, and it automatically assigns the correct displacement of the intrinsic scales between schemes. The variation of the prediction away from the PMC scale exposes the non-zero $\{\beta^R\}$-dependent terms. The PMC prediction does have small residual dependence on the initial choice of scale due to the truncated unknown higher order $\{\beta^R\}$-terms, which will be highly suppressed by proper choice of PMC scales.

- The PMS chooses the renormalization scale such that the first derivative of the fixed-order calculation with respect to the scale vanishes. However, this criterion of minimal sensitivity gives predictions which are not the same as the conformal prediction, and the PMS prediction depends on the choice of renormalization scheme $9$, and it disagrees with QED scale-setting in the Abelian limit. For example, in the case of $e^+e^- \rightarrow gq\bar{q}$, the PMS scale decreases with increasing gluon jet mass and increasing flavor number, opposite to the correct physical behavior [52]. Most important, the PMS does not satisfy the RG-properties of Symmetry, Reflexivity, and Transitivity, so that relations between observables depend on the choice of the intermediate renormalization scheme.

VI. SUMMARY

The conventional scale-setting procedure assigns an arbitrary range and an arbitrary systematic error to fixed-order pQCD predictions. As we have discussed in this article, this ad hoc assignment of the range and associated systematic error is unnecessary and can be eliminated by a proper scale-setting method.

Renormalization group invariance [9] states that a physical quantity should be independent of the renormalization scale and renormalization scheme. With the help of the extended RG equations which incorporate the scheme parameters, we have presented a general demonstration for the RG-invariance by setting the perturbative series up to infinite orders.

We have discussed the necessary self-consistency conditions for a scale-setting method, such as the Existence and Uniqueness of the renormalization scale, Reflexivity, Symmetry, and Transitivity. These properties are natural deductions of RG-invariance. We have shown that PMC satisfies these requirements, whereas the PMS

---

9 As shown in Ref. [51], by using the PMS together with the scheme-equations (7) and the scheme-independent equation (10), such renormalization scheme dependence can be reduced to a certain degree through an order-by-order procedure.
does not. We have also pictorially argued that the formalism based on the extended RG equations satisfies all these requirements for scale and scheme variation.

The principle of minimum sensitivity (PMS) requires that the slope of the approximant of an observable to vanish at the renormalization point. With the help of the extended RG equation, it has been argued that PMS can provide renormalization-scheme dependent estimates \[7\]–\[10\]. However, we have shown that the PMS violates the Symmetry and Transitivity properties of the renormalization group, and it does not reproduce the Gell Mann-Low scale for QED observables. Eq.\[51\] shows that the relation between any two physical observables after PMS scale-setting depends on which renormalization scheme chosen for the calculation, which explicitly breaks the “group properties” of the RG equations. In addition, the application of PMS to jet production gives unphysical results \[52\], since it sums physics into the running coupling not associated with renormalization.

In contrast, the principle of maximum conformity (PMC) provides a fundamental and systematic way to set the optimized renormalization scale at fixed order in pQCD. The PMC has a solid theoretical background \[22\]–\[28\], it provides the underlying principle for BLM, and many PMC features have already been noted in the BLM literature. Most important, it is found after standard PMC scale-setting, the theoretical prediction is essentially independent of the choice of initial renormalization scale and the theorist’s choice of renormalization scheme, consistent with the RG invariance.

The most important goal for a scale-setting method is to eliminate the renormalization scheme and initial scale dependences – more fundamental requirements than improving convergence of the pQCD series. In the literature, however, some extensions of BLM scale-setting have concentrated on how to improve the pQCD convergence, such as the large \(\beta_0\)-expansion \[53\], the sequential BLM (seBLM) and xBLM \[28\]–\[31\], etc.. In fact, once one sets the scales properly, as PMC does, much better pQCD convergence than the conventional scale-setting method is automatic, since the divergent “renormalon” series with \(n!\)-growth disappears. An example of this improved convergence can be found in our analysis for the top-quark pair production at the NNLO level \[12\]–\[14\].

Two more subtle points for PMC scale-setting:

1. In some specific kinematical regions, such as for the heavy quark pair production in the threshold region, Coulomb-type corrections will lead to sizable contributions which are enhanced by factors of \(\pi/\nu\) and the PMC scale can be relatively soft for \(\nu \rightarrow 0\) (\(\nu\), the heavy quark velocity). Thus the terms which are proportional to \((\pi/\nu)\) or \((\pi/\nu)^2\) should be treated separately in that different PMC scales are adopted in the estimation \[19\], \[34\].

2. The factorization scale \(\mu_f\) which enters into the predictions for QCD inclusive reactions is introduced to match nonperturbative and perturbative aspects of the parton distributions in hadrons. The factorization scale occurs even for a conformal theory with \(\{\beta_i^R\} = 0\) where \(\alpha_s\) is constant. The factorization scale should be chosen to match the nonperturbative bound state dynamics with perturbative DGLAP evolution. This can be done explicitly for electron-atom or atom-atom inelastic scattering processes in QED using the known bound state dynamics of atoms. This could also be done in hadron physics using nonperturbative models such as AdS/QCD and light-front holography; recent reviews can be found in Refs. \[55\], \[57\]. There is clearly no reason to equate the factorization scale to the renormalization scale \[57\]. We expect that the factorization scale ambiguity will also be reduced by applying the PMC scale-setting to the kernels of DGLAP evolution equations.

In summary, the application of the PMC eliminates a serious systematic scale-error in pQCD predictions, thus greatly improving the precision of tests of the Standard Model and the sensitivity to new physics at the colliders.
