We show that an isotropic dipolar particle in the vicinity of a substrate made of nonreciprocal plasmonic materials can experience a lateral Casimir force and torque when the particle’s temperature differs from that of the slab and the environment. We connect the existence of the lateral force to the asymmetric dispersion of nonreciprocal surface polaritons and the existence of the lateral torque to the spin-momentum locking of such surface waves. Using the formalism of fluctuational electrodynamics, we show that the features of lateral force and torque should be experimentally observable using a substrate of doped Indium Antimonide (InSb) placed in an external magnetic field, and for a variety of dielectric particles. Interestingly, we also find that the directions of the lateral force and the torque depend on the constituent materials of the particles, which suggests a sorting mechanism based on lateral nonequilibrium Casimir physics.

Nonreciprocal electromagnetic surface waves can occur at an interface between two semi-infinite bulk regions, at least one of which breaks reciprocity. Notable examples include surface waves at the interface between gyrotropic medium and regular dielectric as well as one-way edge modes at the interface between electromagnetic analogues of topological and regular insulators [1–6]. In many cases, the existence of such nonreciprocal surface states is linked with the nontrivial topological behavior of the bulk region making them fundamentally intriguing [7–9]. They are also useful for practical devices like isolators, circulators, phase shifters and lasers [10, 11].

In this letter, we show that the nonreciprocal surface waves have intriguing fundamental implications for Casimir physics [12, 13]. As illustrated in Fig. 1, we consider an exemplary system comprising a reciprocal nanoparticle in the vicinity of a gyrotropic plasmonic substrate, consisting of a doped InSb slab in the presence of a magnetic field, \( B = 1 \text{T} \), applied parallel to its surface. The slab supports nonreciprocal surface plasmon polaritons (SPPs) whose asymmetric dispersion \((\omega(k) \neq \omega(-k))\) is depicted in the inset under a Voigt configuration. These SPPs carry not only linear momentum but also spin angular momentum locked transverse to the linear momentum [14, 15]. When the particle’s temperature \((T_p)\) differs from the temperature of its surroundings including the slab \((T_e)\), there is a net exchange of quantum- and thermal-fluctuations-generated photons between the particle and the nonreciprocal SPPs. Since the resulting exchange of linear momentum and spin angular momentum is asymmetric with respect to forward and backward SPPs, the particle experiences a lateral nonequilibrium Casimir force \((F_y)\) transverse to applied magnetic field, and a lateral nonequilibrium Casimir torque \((M_x)\) parallel to magnetic field.

We provide a rigorous fluctuational electrodynamics analysis of these effects applicable to a particle in the vicinity of a bianisotropic substrate, not limited to the Voigt configuration of the schematic. Instead of the

FIG. 1. We illustrate nonequilibrium lateral Casimir force and torque on an isotropic dipolar nanoparticle in the near field of a doped InSb slab placed in magnetic field parallel to its surface. We assume \( B = 1 \text{T} \) is applied along \( x \) axis of the geometry and clarify the asymmetric interaction of the particle with nonreciprocal SPPs of the slab along \( y \) axis (Voigt configuration). The asymmetric dispersion shown in the inset reveals the unequal magnitude of linear momentum for forward and backward SPPs of equal frequency. The SPPs also carry transverse spin angular momentum locked to their momentum as displayed. When the particle’s temperature \( T_p \) is different from the temperature \( T_e \) of the rest of the system, the net exchange of linear and spin angular momentum via fluctuations-generated photons is asymmetric with respect to forward and backward SPPs causing a lateral force transverse to applied field \((F_y)\) and a lateral torque parallel to applied field \((M_x)\).
usual trace formulas in Casimir physics, we provide semi-analytic expressions for force and torque which are more transparent in capturing the flow of energy, linear and angular momenta between the particle and the SPPs. Using these expressions, we prove that a lateral force and torque on an isotropic particle are not possible for reciprocal media, or for either reciprocal or nonreciprocal media under equilibrium condition \( T_p = T_c \). Moreover, since the particle interacts with large-wavevector SPPs where nonlocal dielectric response cannot be ignored, we use a nonlocal hydrodynamic magnetoplasma model of InSb which indicates the absence of strictly unidirectional SPPs \([16]\). Our calculations show that the lateral force and torque arise because of nonreciprocity, and do not require strictly unidirectional states.

Fluctuational phenomena in nonreciprocal systems is an emerging research topic with recent theoretical proposals for new fundamental effects \([17–20]\) and practical applications \([21–24]\) related to radiative heat transfer. Recent works on this topic explored the effects of nonreciprocity on Casimir torque and force for closely separated plates \([25, 26]\) and torque for individual sphere \([27]\) or closely-separated cubes \([28]\). However, the important fundamental connection between the properties of nonreciprocal surface waves and the behaviors of nonequilibrium Casimir forces and torques has not been discussed previously. Moreover, experiments probing these effects are challenging in plate-plate geometry \([25, 26]\) because they are quite weak due to the large inertia of bulk plates. In contrast, our concrete predictions for a sphere-plate geometry indicate that these effects can be readily detected in modern Casimir \([12, 13]\) and nanoscale heat transfer \([29, 30]\) experiments. We also reveal interesting dependence of directionals of the lateral features on the material composition of the particle. We note that the lateral Casimir forces for equilibrium systems have been studied previously in Ref. \([31–35]\). In these systems, lateral force can only arise from nonuniform lateral configurations. In contrast, lateral nonequilibrium Casimir force in our nonreciprocal system can arise despite the translational invariance of the substrate in the lateral directions.

**Theory:** We consider a dipolar particle characterized by isotropic polarizability tensor \( \alpha_{ij} = \alpha_0 l_{3x3} \) and placed at a distance \( d \) from a generic bianisotropic planar substrate. The particle is at temperature \( T_p \) and the entire environment surrounding the particle, including the substrate and the vacuum half-space, is at temperature \( T_c \). Using fluctuational electrodynamics (see supplement for full derivation), we obtain the following semi-analytic expressions for the spectral density of net power transfer from the particle to the environment \( (P) \) as well as force \( (F_j) \) and torque \( (M_j) \) for \( j \in [x, y, z] \) on the particle:

\[
P(\omega) = (\Theta_{T_p} - \Theta_{T_c}) k_0^2 \text{Im}\{\alpha_0(\omega)\} \left[ \frac{k_0}{\pi} + \int_0^\infty dk_\parallel \int_0^{2\pi} d\phi \text{Im}\left( \frac{ik_\parallel e^{2ik_\parallel d}}{8\pi^2 k_z} [r_{ss} + r_{pp}(2k_\parallel^2/k_0^2 - 1)] \right) \right]
\]

\[
F_x(\omega) = -(\Theta_{T_p} - \Theta_{T_c}) \frac{k_0}{c} \text{Im}\{\alpha_0(\omega)\} \int_0^\infty dk_\parallel \int_0^{2\pi} d\phi \text{Im}\left( \frac{ik_\parallel e^{2ik_\parallel d}}{8\pi^2 k_z} [r_{ss} + r_{pp}(2k_\parallel^2/k_0^2 - 1)] k_\parallel \cos \phi \right)
\]

\[
F_y(\omega) = -(\Theta_{T_p} + \Theta_{T_c}) \frac{k_0}{c} \text{Im}\{\alpha_0(\omega)\} \int_0^\infty dk_\parallel \int_0^{2\pi} d\phi \text{Im}\left( \frac{ik_z e^{2ik_z d}}{8\pi^2} [r_{ss} + r_{pp}(2k_z^2/k_0^2 - 1)] \right)
\]

\[
M_z(\omega) = -(\Theta_{T_p} - \Theta_{T_c}) \frac{k_0}{c} \text{Im}\{\alpha_0(\omega)\} \int_0^\infty dk_\parallel \int_0^{2\pi} d\phi \frac{k_z^2}{8\pi^2 k_0^2} \left[ \cos \phi \text{Im}\left( \frac{(r_{sp} - r_{ps}) e^{2ik_z d}}{k_z} \right) + 2 \sin \phi \text{Im}\left( \frac{r_{pp} e^{2ik_z d}}{k_z} \right) \right]
\]

\[
M_x(\omega) = (\Theta_{T_p} - \Theta_{T_c}) \frac{k_0}{c} \text{Im}\{\alpha_0(\omega)\} \int_0^\infty dk_\parallel \int_0^{2\pi} d\phi \left( \frac{k_\parallel}{8\pi^2 k_0^2} \text{Im}\left( (r_{sp} + r_{ps}) e^{2ik_\parallel d} \right) \right)
\]

\[
F_y(\omega) = F_x(\omega, \cos \phi \rightarrow \sin \phi), \quad M_y(\omega) = M_x(\omega, \cos \phi \rightarrow \sin \phi, \sin \phi \rightarrow -\cos \phi)
\]

Here, \( \Theta_T(\omega, T) = \hbar \omega/2 + \hbar \omega/[\exp(\hbar \omega/k_B T) - 1] \) is the mean energy of a harmonic oscillator of frequency \( \omega \) at thermodynamic temperature \( T \). Total power, force, torque are obtained by integrating corresponding spectral density over all frequencies as \( Q^j = \int_{-\infty}^{\infty} Q(\omega) d\omega/2\pi \) where \( Q = \{P, F_j, M_j\} \). The term outside the wavevector integration in Eq. 1 comes from the heat transfer between the particle and the vacuum half-space. Such transfer does not lead to any force or torque for an isotropic particle. The terms inside the wavevector integration indicate the interaction between the particle and the substrate via quantum- and thermal-fluctuations-generated photons characterized by their frequency \( \omega \) and in-plane wavevector components \( (k_x = k_\parallel \cos \phi, k_y = k_\parallel \sin \phi) \) where \( \phi \) is the angle with \( x \) axis of the geometry. \( k_z \) is the perpendicular wavevector.
component such that $k^2_j + k^2_z = k^2_0$ where $k_0 = \omega/c$. $r_{jk}$ for $j, k \in [s, p]$ denotes the Fresnel reflection coefficient which is the amplitude of $j$-polarized reflected light under incident unit-amplitude $k$-polarized light characterized by $(\omega, k_\parallel, \phi)$. Electromagnetic response of the substrate enters through the reflection coefficients. Here we assume that there are no relative translational or rotational motions between the particle and the substrate. In the presence of such relative motions, Eqs.(1)-(6) will need to be modified to take into account resulting Doppler shift in the frequency of photons being exchanged [27, 36–38]. The extension of Eqs.(1)-(6) taking into account the rotation of the particle, is provided in the supplement. We also note that the correction due to such relative motions are in general quite small since these motions are usually in the non-relativistic regime. Thus, in practice, Eqs.(1)-(6) should be sufficient for most experimental situations.

We note that all components of force and torque can be separately derived by dividing the integrand in the power spectral density [Eq. 1] by the photon energy $\hbar \omega$, multiplying by linear momentum vector $\hbar (k_\parallel \cos \phi, k_\parallel \sin \phi, k_z)$ and spin angular momentum vector $\hbar (\sin \phi, -\cos \phi, 0)$ of polaritons, and accounting for whether the photon is emitted or absorbed by the particle. This physically meaningful alternative derivation is exact for force calculation but approximate for torque calculation because the spin angular momentum $\hbar (\sin \phi, -\cos \phi, 0)$ is exact only for large wavevector polaritons ($k_\parallel \gg k_0$) [also proved separately in the supplement]. The alternative derivation reveals the intimate connection between energy, linear and angular momentum transfer in our system.

Equations 2-6 are consistent with some of the general physics constraints. At thermal equilibrium ($\Theta_{T_e} = \Theta_{T_m}$), all force and torque components as predicted by Eqs. 2-6 are zero except the perpendicular force $F_z$. This follows from the observation that the Casimir free energy of the system depends on the vertical displacement $d$ between the particle and the substrate but not the lateral displacement. For a substrate made of reciprocal media, the Fresnel coefficients satisfy the reciprocity constraints $r_{ss, pp}(k_\parallel, \phi) = r_{ss, pp}(k_\parallel, \phi + \pi)$ and $r_{sp}(k_\parallel, \phi) = -r_{ps}(k_\parallel, \phi + \pi)$ [24, 39]. By integrating Eqs. 2 to 6, it follows that there is no lateral force and no lateral torque on the particle in the near field of a reciprocal medium, for both equilibrium and nonequilibrium scenarios. For a nonreciprocal medium, the reciprocity constraints no longer hold and therefore, one can expect to see nontrivial effects for the nonequilibrium scenarios. Therefore, we consider a substrate made of doped InSb with external magnetic field which results in a strong nonreciprocity in its electromagnetic response. The reflection coefficients in equations 1 to 6 are obtained by solving the boundary conditions at the interface [16].

**Results:** We consider both a local model and a nonlocal model [16] for the permittivity of InSb to highlight some of the consequences of the nonlocal dielectric response. Figure 2(a) shows the frequency-dependent local permittivity ($\epsilon_{jk}(\omega)$ for $j, k = [x, y, z]$) of InSb slab in presence of magnetic field $B = 1T$ applied along x axis. The variation of diagonal components reveals the approximate locations of the surface phonon (higher branch) and plasmon (lower branch) polaritons, henceforth denoted by the acronym SPhP and SPP, respectively. Fig. 2(b) shows the polaritonic dispersion ($\omega(k_\parallel)$) of nonreciprocal SPPs propagating in different directions. Since the behavior is the same for
nonreciprocal SPhPs, we focus on SPPs in this figure. As shown in the inset, because of the Zeeman interaction between the spin magnetic moment of nonreciprocal surface polaritons and the magnetic field \( [19] \), the polaritons making an angle \( \phi \in [0, \pi] \) with B-field and carrying positive momentum \( k_y > 0 \) experience a redshift whereas the polaritons characterized by \( \phi \in [\pi, 2\pi] \) or \( k_y < 0 \) experience a blueshift compared to the dispersion in the absence of the magnetic field \( (B = 0) \). Based on the momentum \( k_y \), the red-shifted polaritons can be collectively interpreted as forward waves and blue-shifted polaritons as backward waves. Due to these opposite frequency shifts, the forward and backward momentum waves of equal frequency carry very different momentum and experience unequal near-field coupling with the particle (proportional to \( e^{-2|k_y|d} \) in Eqs. 1-6), leading to a lateral Casimir force and torque.

Figure 2(b) shows the SPP dispersion using both a nonlocal model (solid lines) and a local model (dashed lines). At large wavevectors, \( \omega(k_y) \) increases based on a nonlocal model while it reaches a constant value based on a local model. While this reveals a stark contrast between the two models pertaining to presence or absence of strictly unidirectional SPPs [16], we note that the lateral force and torque arise due to opposite frequency shifts of forward and backward waves noted above, which occurs for both local and nonlocal models and does not require strict unidirectionality. Nonetheless, the magnitudes of force and torque are slightly different as we show further below. Unless noted otherwise, all results below are generated using a nonlocal model.

To highlight the effects of the nonreciprocal surface waves, we first calculate the spectral densities in Eqs. 2-6 assuming a frequency-independent polarizability, \( \text{Im}\{\alpha(\omega)\} = 10^{-19}\text{m}^{-3} \) for the particle. We use the temperatures \( T_p = 305\text{K} \) and \( T_e = 300\text{K} \). We find that \( F_y(\omega) \), \( M_y(\omega) \), \( M_x(\omega) \) are identically zero for this configuration. We do not discuss the perpendicular Casimir force \( F_z(\omega) \) here since its behavior is well known, and focus instead on the lateral effects. Figure 2(c) demonstrates the force spectral density (black line) when the center of the particle is at a distance \( d = 0.3\mu\text{m} \) from the surface along with the separate collective contributions of red-shifted polaritons (red dashed line) and blue-shifted polaritons (blue dashed line). In the case of \( T_p > T_e \), there is a net emission from the particle to the substrate. The emission to red-shifted and blue-shifted polaritons provides a negative \( (F_y < 0) \) and positive \( (F_y > 0) \) contribution to the force, from linear momentum conservation, as they carry positive \( (k_y > 0) \) and negative \( (k_y < 0) \) momentum, respectively. The difference in these two contributions arising from the nonreciprocity in the dispersion of surface waves, results in the lateral Casimir force. Fig. 2(d) demonstrates the torque spectral density (black line) where the sign of the torque follows from the separate contributions of red-shifted and blue-shifted polaritons carrying positive and negative transverse spin (along \( x \) axis) respectively, and based on angular momentum conservation. And again, the difference in these two collective contributions causes the lateral Casimir torque.

Figure 2(e) also highlights the asymmetry in the net power transfer from the particle to forward and backward nonreciprocal surface waves and the resulting spectrally broadened total contribution (black line). Figure 2(f) plots the force spectral density based on local and nonlocal models. The local model overestimates the magnitude of the force and its spectrum is red-shifted compared to that obtained using the nonlocal model.

To estimate the magnitude of the total lateral force and torque in potential experiments, we consider various nanoparticles (PbTe, AgBr, CdTe, AgCl, NaCl, ZnSe, undoped InAs) of radius \( R = 200\text{nm} \) whose polarizability response functions are shown in Fig.3(a). The material permittivity \( \epsilon(\omega) \) is obtained from various references [40–42] and the polarizability is calculated as \( \alpha(\omega) = 4\pi R^3[\epsilon(\omega) - 1]/[\epsilon(\omega) + 2] \) using a dipolar approximation which is fairly accurate since the particle radius is much smaller than the relevant wavelengths of 45-90\( \mu\text{m} \) (deep subwavelength regime). The stated materials were chosen because they exhibit a strong resonant response in

![FIG. 3. (a) We consider nanoparticles of radius \( R = 200\text{nm} \) and made of different materials such that they exhibit dipolar resonances over the frequency range of interest. (b,c) demonstrate the dependence of force and torque on surface-to-surface distance \( d_s = d - R \) for AgBr (red) and NaCl (blue) nanoparticles for two different operating temperatures \( T_p = 310\text{K} \) (solid lines) and \( T_p = 500\text{K} \) (dashed lines) assuming \( T_e = 300\text{K} \). (d) We consider a potential experiment where the same AgBr and NaCl particles are trapped near InSb slab in \( B = 17\text{T} \) inside a vacuum chamber of pressure \( 10^{-9}\text{torr} \). The particles reach a steady state angular velocity at which the Casimir torque is balanced by the rotational drag of imperfect vacuum. The figure plots the distance dependence of steady-state rotational velocities for operating temperatures \( T_p = 310\text{K} \) and \( T_e = 300\text{K} \).](image-url)
the aforementioned frequency range. By comparing the resonant frequency of the particle with the frequencies of red-shifted and blue-shifted nonreciprocal SPPs and SPhPs of InSb, we can deduce the directionalities of the lateral force and torque. Assuming warm particles \( (T_p > T_e) \), it follows that AgBr, PbTe particles experience \( F^y_0 < 0 \) and \( M^z_t > 0 \) since they emit photons dominantly to red-shifted SPPs while all other particles experience \( F^y_0 > 0 \) and \( M^z_t > 0 \) since they emit photons dominantly to blue-shifted SPPs or SPhPs. The opposite force behavior for different materials suggests that it might be possible to use such lateral Casimir force to sort particles based on the material composition.

Figure 3(b, c) demonstrate the distance dependence of lateral force and torque on AgBr (red lines) and NaCl (blue lines) particles of radius \( R = 200nm \) for temperatures \( T_p = 310K \) (solid lines) and \( T_p = 500K \) (dashed lines) assuming \( T_e = 300K \). The magnitudes of force and torque increase as the particle’s temperature increases. For both choices of \( T_p \), their magnitudes increase as the particle-surface separation decreases. For NaCl particle at \( T_p = 500K \), lateral force \( F^y_0 \sim 10^{-16}N \) and lateral torque \( M^z_t \sim 10^{-23}Nm \) are observed when the vacuum gap spacing between the particle and the substrate is reduced to few nanometers. Such a force is in fact comparable to the force of gravity on the particle. For NaCl particle of mass density \( \rho = 2.165g/cm^3 \), gravity force is \( W = 7.3 \times 10^{-17}N \). For AgBr particle of mass density \( \rho = 6.47g/cm^3 \), gravity force is \( W = 2.17 \times 10^{-16}N \). Ultrasonically detection of force of magnitude \( 10^{-20}N \) and torque of magnitude \( 10^{-27}Nm \) have been realized in experiments [2, 13, 43, 44]. Other recent experiments have measured near-field heat transfer at nanoscale under large temperature differentials [29, 30, 45–47]. In Ref. [30], temperature differences larger than \( 100K \) were maintained between a tip and a plate separated by \( 2nm \). Therefore, we are optimistic that the experimental demonstration of our predictions should be feasible.

We also consider an alternative experiment where the particle is optically levitated in the near field of InSb slab inside a vacuum chamber. Due to the Casimir torque, the particle experiences angular acceleration. As its angular velocity increases, it experiences an oppositely directed rotational drag torque due to residual gas molecules of the imperfect vacuum. Eventually, such a particle will reach a steady-state angular velocity at which the nonequilibrium Casimir torque is balanced by the rotational drag torque. Assuming a vacuum chamber of gas pressure \( 10^{-5} \) torr, Fig. 3(d) shows the steady state rotational velocities for levitated AgBr (red) and NaCl (blue) particles under temperature difference of \( T_p - T_e = 10K \) (see supplement for more details). As displayed, the particles rotate with opposite angular velocities and they reach rotational velocities in the MHz-GHz range depending on their distance from the surface. Such rotations could be detected in experiments. We note that the nonreciprocity-induced nonequilibrium torque was recently analyzed for a single gyrotropic particle [27] and for two finite-size gyrotronic particles separated by small distance [28]. The magnitude of torque in our work is few orders of magnitude larger than the values reported in the previous studies due to the large density of surface polariton states in the near field of a gyrotronic substrate [48]. We also note that the magnitudes of the lateral nonequilibrium Casimir force and torque can be further enhanced using Weyl semimetals [49] which provide much stronger gyrotropy compared to InSb considered here.

**Conclusion:** We demonstrated that nonreciprocal surface waves can lead to a nonequilibrium lateral Casimir force and torque on an isotropic nanoparticle. We clarified the origin of these effects by transparently accounting for the underlying asymmetric flow of energy and momenta. We connected the lateral force to the dispersion of nonreciprocal surface polaritons and the lateral torque to the spin-momentum locking. We also made predictions for potential experiments to detect these nonreciprocal Casimir effects soon. Our work indicates intriguing opportunities at the intersection of nonreciprocity, photon spin, Casimir physics and topological materials.

(Dated: June 22, 2021)

We derive the semi-analytic expressions for power, force and torque spectral densities provided in the main text using fluctuational electrodynamics. For making predictions for potential experiments, we rigorously analyze the rotational dynamics of the nanoparticle in a vacuum chamber, taking into account an additional rotational friction arising from the residual air molecules. While the Casimir torque is derived assuming a non-rotating particle, we also prove that this derivation is accurate as long as the particle’s rotational angular velocity (Ω) is much smaller than the relevant thermal fluctuations frequencies (ω ≈ 10^13 rad/s). We separately derive and plot the angular-velocity-dependent Casimir torque.

I. FLUCTUATIONAL ELECTRODYNAMIC DERIVATION OF POWER, FORCE AND TORQUE

We consider a dipolar spherical particle of polarizability α_jk = α_0\mathcal{I}_{3x3} placed at a distance d from the semi-infinite half-space of a generic linear, time-invariant bianisotropic medium. The particle is at thermodynamic temperature T_p and the rest of the system, denoted as the environment is at temperature T_e. Using fluctuational electrodynamics, the spectral densities of the net power transfer from the particle to the environment P(ω), the force F_j(ω) and the torque M_j(ω) on the particle for j = [x, y, z] are [1, 2]:

\[ P(ω) = ω \text{Im}[\langle p_{j}^\text{fl}(ω)p_{j}^\text{ind}(ω)\rangle + \langle p_{j}^\text{ind}∗(ω)p_{j}^\text{fl}(ω)\rangle] \] (1)
\[ F_j(ω) = \text{Re}[\langle p_{j}^\text{fl}(ω)\partial_j E_k^\text{ind}∗(ω)\rangle + \langle p_{j}^\text{ind}(ω)\partial_j E_k^\text{fl}(ω)\rangle] \] (2)
\[ M_j(ω) = \varepsilon_{ijk}\text{Re}[\langle p_{j}^\text{fl}(ω)E_l^\text{ind}∗(ω)\rangle + \langle p_{j}^\text{ind}(ω)E_l^\text{fl}(ω)\rangle] \] (3)

where Einstein summation convention is used with j, k, l ∈ [x, y, z]. \(\langle \cdots \rangle\) denotes statistical ensemble average of the fluctuating quantities enclosed within. These physical quantities are expressed in SI units and the total power, force, torque are obtained by integrating over both positive and negative frequencies as \(Q^t = \int_{−∞}^{∞} Q(ω)dω/2π\) where \(Q = \{P, F_j, M_j\}\). Here \(p_{j}^\text{ind} = ϵ_0α_{jk}E_k^\text{ind}\) is the dipole moment induced in the particle by the environment field fluctuations. \(E_j^\text{ind}\) is the field at the dipole location by the fluctuating dipole moment itself. In general, the field \(E_j^\text{ind}(r_2, ω)\) at an arbitrary location \(r_2\) generated by the dipole moment \(p_{j}^\text{fl}(r_1, ω)\) at the spatial position \(r_1\) is given by \(E_j^\text{ind}(r_2, ω) = ω^2μ_0G_{jk}(r_2, r_1, ω)p_{j}^\text{fl}(r_1, ω)\) where \(G_{jk}(r_2, r_1, ω)\) is the Green’s function. The semi-analytic form of Green’s function in the dipole-plate geometry considered here is [3]:

\[
\overline{G}(r_1, r_2, ω) = \int \frac{d^2k_∥}{(2π)^2}e^{i\mathbf{k}_∥(\mathbf{r}_1−\mathbf{r}_2)}\frac{i}{2\kappa_z} \left[ e^{ik_z(z_1−z_2)}[\mathbf{e}_{±s}^T\mathbf{e}_{±s} + \mathbf{e}_{p±}^T\mathbf{e}_{p±}] \\
+ e^{ik_z(z_1+z_2)}[(r_{ss}\mathbf{e}_{s±} + r_{ps}\mathbf{e}_{p±})\mathbf{e}_{±s}^T + (r_{sp}\mathbf{e}_{s±} + r_{pp}\mathbf{e}_{p±})\mathbf{e}_{±p}^T]\right]
\]

(4)

where \(\mathbf{r} = (\mathbf{R}, z)\) is the position vector. \(\mathbf{k}_∥ = (k_∥ \cos φ, k_∥ \sin φ)\) is the in-plane momentum such that φ is the angle with x axis of the geometry. \(k_z\) is the perpendicular wavevector component such that \(k_z^2 + k_∥^2 = k_0^2\) where \(k_0 = ω/c\). \(r_{jk}\) for \(j, k \in [s, p]\) denotes the Fresnel reflection coefficient which is the amplitude of j-polarized reflected light when unit-amplitude k-polarized light characterized by \((ω, k_∥, φ)\) is incident. The polarization vectors \(\mathbf{e}_{j±}\) for \(j = [s, p]\) for
waves going along \( \pm \hat{e}_z \) direction are:

\[
\hat{e}_{s\pm} = \begin{bmatrix} \sin \phi \\ -\cos \phi \\ 0 \end{bmatrix}, \quad \hat{e}_{p\pm} = \frac{-1}{k_0} \begin{bmatrix} \pm k_z \cos \phi \\ \pm k_z \sin \phi \\ -k_\parallel \end{bmatrix}
\]

(5)

The calculation of the power, force, torque in Eq. 1-3 relies on \( p_0^\parallel \) and \( E_j^\parallel \) which denote statistically uncorrelated particle dipole moment fluctuations and environment field fluctuations at the dipole location respectively. They satisfy the following fluctuation dissipation theorems (FDTs) based on linear response theory [4]:

\[
\langle p_j^\parallel (\omega)p_k^{\parallel*} (\omega') \rangle = \frac{\alpha_{jk}(\omega) - \alpha_{kj}^*(\omega)}{2i}\frac{\epsilon_0}{\omega} \Theta_{T_p}(2\pi)\delta(\omega - \omega')
\]

(6)

\[
\langle E_j^\parallel (r_1, \omega)E_k^{\parallel*} (r_2, \omega') \rangle = \frac{G_{jk}(r_1, r_2, \omega) - G_{kj}^*(r_2, r_1, \omega)}{2i} \mu_0 \omega \Theta_{T_e}(2\pi)\delta(\omega - \omega')
\]

(7)

where \( \langle \cdots \rangle \) denotes the statistical ensemble average and \( \Theta_{T}(\omega, T) = \hbar \omega / [\exp(\hbar \omega/k_B T) - 1] \) is the Planck’s function giving the mean energy of a harmonic oscillator at thermodynamic temperature \( T \). In the derivation of the above spectra [Eqs.1,2,3] from the real-valued dipole moment \( p_j(t) = \int_{-\infty}^{\infty} \frac{dx}{2\pi} p_j(\omega) e^{-i\omega t} \) and electric field \( E_j(t) = \int_{-\infty}^{\infty} \frac{dx}{2\pi} E_j e^{-i\omega t} \), the factor of \((2\pi)\) in the above FDTs gets cancelled upon integration over frequency \( \omega' \) and only equal frequency correlations survive.

A. Derivation of radiated power

The net power transfer from the particle to the environment is obtained using Eqs. 1,4,6,7. The power exchanged with the vacuum part of the geometry corresponding to the vacuum part of the Green’s function [in Eq. 4] is given below:

\[
P_{\text{vac}}(\omega) = \frac{\omega^3}{\pi \epsilon_0} \text{Im} \{ \alpha_0(\omega) \} \{ \Theta_{T_p} - \Theta_{T_e} \}
\]

(8)

The radiated power corresponding to the reflected part of the Green’s function in Eq. 4, henceforth abbreviated as \( G_{jk}^{\text{ref}}(r_1, r_2, \omega) \), and originating from the particle dipole moment fluctuations [Eq.6] is:

\[
P_{\text{ref}}^p(\omega) = \omega^3 \mu_0 \epsilon_0 \Theta_{T_p} \text{Im} \{ \alpha_0(\omega) \} \text{Im} [ \text{Tr} (G_{jk}^{\text{ref}}) ]
\]

\[
\quad = \omega^3 \mu_0 \epsilon_0 \Theta_{T_p} \text{Im} \{ \alpha_0(\omega) \} \text{Im} [ \int \frac{k_{\parallel} dk_{\perp}}{2\pi^2} \frac{2\hbar e^{ik_{\parallel}d}}{2k_z} \{ r_{ss} + r_{pp} \left( \frac{2k_z^2}{k_0^2} - 1 \right) \} ]
\]

(9)

The radiated power corresponding to the reflected part of the Green’s function, and originating from the environment field fluctuations [Eq.7] is:

\[
P_{\text{ref}}^{\text{env}}(\omega) = \omega \text{Im} \{ \epsilon_0 \alpha^*(\omega) (E_j^{\parallel*} E_j^{\parallel}) \}
\]

\[
\quad = \omega \epsilon_0 \mu_0 \omega \Theta_{T_e} \text{Im} \{ \alpha^*(\omega) \text{Im} [ \text{Tr} (G_{jk}^{\text{ref}}) ] \}
\]

\[
\quad = -\frac{\omega^2}{c^2} \Theta_{T_e} \text{Im} \{ \alpha_0(\omega) \} \text{Im} [ \int \frac{k_{\parallel} dk_{\perp}}{2\pi^2} \frac{2\hbar e^{ik_{\parallel}d}}{2k_z} \{ r_{ss} + r_{pp} \left( \frac{2k_z^2}{k_0^2} - 1 \right) \} ]
\]

(10)

The spectrum of the net radiated power from the particle to the environment provided in the main text is obtained by adding together the above expressions.

B. Derivation of force

Because of the rotational symmetry of the spherical particle described by isotropic polarizability, the direct interaction of the particle with vacuum does not lead to any torque or force on the particle. Therefore, we focus
on the force and torque arising from the reflected part of the Green’s function. First, we calculate the force spectrum \[ F_x^\text{env}(\omega) = \text{Re}(\epsilon_0 \partial_x E^\text{b}(r_2)) = \int \frac{d\omega}{2\pi} \text{Re}(\epsilon_0 \partial_x E^\text{b}(r_2)) \] commuting terms

= \text{Re}(\epsilon_0 \partial_x \langle \hat{p}_x \rangle (\hat{r}_1) \hat{r}_1) \hat{r}_2 \rightarrow \hat{r}_1

= \epsilon_0 \partial_x \langle \hat{p}_x \rangle (\hat{r}_1) \hat{r}_1 \hat{r}_2 \rightarrow \hat{r}_1

= \epsilon_0 \mu_0 \omega \Theta_{T_e} \text{Re}(\alpha_0) \left( -ik_x G_{jj}(r_1, r_2) - (-ik_x) G^*_j(r_2, r_1) \right)

= \frac{\omega}{c^2} \Theta_{T_e} \text{Re}(\alpha_0) \left[ \int k_{\parallel} d\phi d\theta \frac{e^{i2k_z d}}{2k_z} \cos \phi \left( r_{ss} + \frac{2k_z^2}{k_0^2} - 1 \right) r_{pp} \right]

Note that for reciprocal media, \( r_{ss,pp}(\phi) = r_{ss,pp}(\phi + \pi) \) because of the time-reversal symmetry. It then follows that upon integration over the angle \( \phi \), the integrand at \( \phi \) cancels with the integrand at \( \phi + \pi \) because of \( \cos \phi \) term, leading to zero parallel force. For nonreciprocal medium, parallel force is not necessarily zero.

Similarly, the \( \hat{e}_z \) component of the force can be calculated. Instead of \( -ik_x \) terms in the above derivation, we will get \( +ik_z \) from the Green’s function, eventually leading to the following expression:

\[ F_z^\text{env}(\omega) = -\frac{\omega}{c^2} \Theta_{T_e} \text{Im}(\alpha_0) \left[ \int k_{\parallel} d\phi d\theta \frac{e^{i2k_z d}}{2k_z} \cos \phi \left( r_{ss} + \frac{2k_z^2}{k_0^2} - 1 \right) r_{pp} \right] \]

Note that for reciprocal media, no cancellation over angular integration occurs and the above expression leads to a force perpendicular to the force for both reciprocal and nonreciprocal media.

We will now calculate the force originating from the particle dipole moment fluctuations:

\[ F_x^P(\omega) = \text{Re}(\partial_x E^\text{ind}(r_2)) \]

\[ = \omega^2 \mu_0 \text{Re}(\hat{p}_x (r_1) \hat{r}_2 \rightarrow \hat{r}_1)

\[ = \omega^2 \mu_0 \text{Re}(\frac{\omega}{\omega} \Theta_{T_p} \text{Im}(\alpha_0) \partial_x G^*_j(r_2, r_1) \hat{r}_2 \rightarrow \hat{r}_1)

\[ = \frac{\omega}{c^2} \Theta_{T_p} \text{Im}(\alpha_0) \left[ k_z G^*_j(r_1, r_1) \right]

\[ = -\frac{\omega}{c^2} \Theta_{T_p} \text{Im}(\alpha_0) \left[ \int k_{\parallel} d\phi d\theta \frac{e^{i2k_z d}}{2k_z} \cos \phi \left( r_{ss} + \frac{2k_z^2}{k_0^2} - 1 \right) r_{pp} \right] \]

For the calculation of force along \( \hat{e}_z \) direction from particle dipole moment fluctuations, the partial derivative \( \partial_z \) leads to \( -ik_z \) instead of \( +ik_z \) (for environment contribution) because of the complex conjugation of the Green’s function i.e. \( G^*_j(r_1, r_1) \). The final expression for the force is:

\[ F_z^P(\omega) = -\frac{\omega}{c^2} \Theta_{T_p} \text{Im}(\alpha_0) \left[ \int k_{\parallel} d\phi d\theta \frac{e^{i2k_z d}}{2k_z} \cos \phi \left( r_{ss} + \frac{2k_z^2}{k_0^2} - 1 \right) r_{pp} \right] \]

The net parallel and perpendicular fluctuations-induced forces acting on the particle are:

\[ F_x(\omega) = \frac{\omega}{c^2} \left( \Theta_{T_e} - \Theta_{T_p} \right) \text{Im}(\alpha_0) \left[ \int k_{\parallel} d\phi d\theta \frac{e^{i2k_z d}}{2k_z} \cos \phi \left( r_{ss} + \frac{2k_z^2}{k_0^2} - 1 \right) r_{pp} \right] \]

\[ F_y(\omega) = F_z(\omega) \cos \phi \rightarrow \sin \phi \]

\[ F_z(\omega) = -\frac{\omega}{c^2} \left( \Theta_{T_e} + \Theta_{T_p} \right) \text{Im}(\alpha_0) \left[ \int k_{\parallel} d\phi d\theta \frac{e^{i2k_z d}}{2k_z} \cos \phi \left( r_{ss} + \frac{2k_z^2}{k_0^2} - 1 \right) r_{pp} \right] \]
C. Derivation of torque

Similar to the calculation of force, we calculate the torque using the reflected part of Green’s function (indicating photons reflected from the surface). The torque \( M_{xy} \) parallel to the surface and originating from the environment field fluctuations is:

\[
M_{xy}^\text{env} (\omega) = \epsilon_0 \text{Re}[\alpha_0 ((E_y E_y^* - E_z E_z^*))] = \int \frac{d\omega}{2\pi} \epsilon_0 \text{Re}[\alpha_0 \times 2i \text{Im}\{E_y E_y^*\}]
\]

\[
= -2\epsilon_0 \mu_0 \omega \Theta_{T_x} \text{Im}\{\alpha_0\} \text{Im}\left[\frac{G_{yz} - G_{yz}^*}{2i}\right]
\]

\[
= -\frac{\omega}{c^2} \Theta_{T_y} \text{Im}\{\alpha_0\} \int \frac{d^2k_y}{(2\pi)^2} \text{Im}\left[-\frac{k_{||}}{2k_0} \cos \phi \left(r_{sp} e^{2ik_z d} + r_{ps} e^{-2ik_z d}\right) - \frac{i k_{||}}{k_0} \sin \phi \text{Im}\left(r_{pp} e^{i2k_z d}\right)\right]
\]

The torque in the direction perpendicular to the surface is:

\[
M_{xy}^\text{env} (\omega) = \text{Re}[\alpha_0 \times 2i \text{Im}\{E_y E_y^*\}]
\]

\[
= -2\epsilon_0 \mu_0 \omega \Theta_{T_x} \text{Im}\left[\frac{G_{xy} - G_{yx}^*}{2i}\right]
\]

\[
= -\frac{\omega}{c^2} \Theta_{T_y} \text{Im}\{\alpha_0\} \int \frac{k_{||}dk_{||}d\phi}{(2\pi)^2} \text{Im}\left[r_{sp} + r_{ps}\right] e^{2ik_z d}\right]
\]

The torque components \( M_{x,z} \) due to photons generated by particle dipole moment fluctuations are:

\[
M_{x}^\text{p} (\omega) = \omega^2 \mu_0 \text{Im}\{\alpha_0\} \text{Re}[G_{yy}^* - G_{yz}]
\]

\[
= \frac{\omega}{c^2} \Theta_{T_x} \text{Im}\{\alpha_0\} \text{Im}[iG_{yy}^* - iG_{yz}]
\]

\[
= 2\frac{\omega}{c^2} \Theta_{T_x} \text{Im}\{\alpha_0\} \text{Im}\left[\frac{G_{yy} - G_{yz}}{2i}\right]
\]

\[
= \frac{\omega}{c^2} \Theta_{T_x} \text{Im}\{\alpha_0\} \int \frac{k_{||}dk_{||}d\phi}{(2\pi)^2} \left[-\frac{k_{||}}{2k_0} \cos \phi \text{Im}\left(r_{sp} - r_{ps}\right) e^{2ik_z d}\right] - \frac{k_{||}}{k_0} \sin \phi \text{Im}\left(r_{pp} e^{i2k_z d}\right)
\]

The torque along \( z \) direction is:

\[
M_{z}^\text{p} (\omega) = 2\frac{\omega}{c^2} \Theta_{T_x} \text{Im}\{\alpha_0\} \text{Im}\left[\frac{G_{xy} - G_{yx}^*}{2i}\right]
\]

\[
= \frac{\omega}{c^2} \Theta_{T_x} \text{Im}\{\alpha_0\} \int \frac{k_{||}dk_{||}d\phi}{(2\pi)^2} \frac{k_{||}}{2k_0} \cos \phi \text{Im}\left(r_{sp} - r_{ps}\right) e^{2ik_z d}\right] + \frac{k_{||}}{k_0} \sin \phi \text{Im}\left(r_{pp} e^{i2k_z d}\right)
\]

The final expressions for the fluctuations-induced torque spectrum are:

\[
M_x (\omega) = \frac{\omega}{c^2} \Theta_{T_x} \text{Re}\{\Theta_{T_y} - \Theta_{T_p}\} \text{Im}\{\alpha_0\} \int \frac{k_{||}dk_{||}d\phi}{(2\pi)^2} \left[-\frac{k_{||}}{2k_0} \cos \phi \text{Im}\left(r_{sp} - r_{ps}\right) e^{2ik_z d}\right] + \frac{k_{||}}{k_0} \sin \phi \text{Im}\left(r_{pp} e^{i2k_z d}\right)
\]

\[
M_y (\omega) = \frac{\omega}{c^2} \Theta_{T_x} \text{Re}\{\Theta_{T_y} - \Theta_{T_p}\} \text{Im}\{\alpha_0\} \int \frac{k_{||}dk_{||}d\phi}{(2\pi)^2} \left[-\frac{k_{||}}{2k_0} \sin \phi \text{Im}\left(r_{sp} - r_{ps}\right) e^{2ik_z d}\right] - \frac{k_{||}}{k_0} \cos \phi \text{Im}\left(r_{pp} e^{i2k_z d}\right)
\]

\[
M_z (\omega) = -\frac{\omega}{c^2} \Theta_{T_x} \text{Re}\{\Theta_{T_y} - \Theta_{T_p}\} \text{Im}\{\alpha_0\} \int \frac{k_{||}dk_{||}d\phi}{(2\pi)^2} \frac{1}{2k_0} \text{Im}\left(r_{sp} + r_{ps}\right) e^{i2k_z d}\right]
\]

For reciprocal media, \( r_{sp,pp}(\theta, \phi) = r_{sp,pp}(\theta, \phi + \pi) \) and \( r_{ps}(\theta, \phi) = -r_{ps}(\theta, \phi) \). By summing the integrands at \( \phi \) and \( \phi + \pi \), it follows that particle does not experience any torque. For InSb slab with magnetic field parallel to the surface, this is no longer true and a lateral torque parallel to surface is observed. However, the Fresnel coefficients for this system also satisfy the condition \( r_{sp} + r_{ps} = 0 \) [5] leading to a zero torque along \( z \) axis.
We note that all components of force and torque can be derived by dividing the integrand in the power spectrum by energy $\hbar \omega$, multiplying by linear momentum vector $\hbar (k_{\parallel} \cos \phi, k_{\parallel} \sin \phi, k_z)$ and spin angular momentum vector $\hbar (\sin \phi, -\cos \phi, 0)$ of polaritons, and accounting for whether the photon is emitted or absorbed by the particle. This physically meaningful alternative derivation is exact for force calculation which is evident from the final expressions of the spectra above. It is approximate for torque because the spin angular momentum $\hbar (\sin \phi, -\cos \phi, 0)$ is exact only for large wavevector polaritons ($k_{\parallel} \gg k_0$). This is proved in the following. We can calculate the angular momentum transferred for each photon exchanged which is characterized by $(\omega, k_{\parallel}, \phi)$:

$$M_x(\omega, k_{\parallel}, \phi) = \frac{k_1}{2k_0} \cos \phi \text{Im} \left( \frac{(r_{sp} - r_{ps}) e^{2ik_z d}}{k_z} + \frac{k_1}{k_0} \sin \phi \text{Im} \{r_{pp} e^{2ik_z d} \} \right) \hbar$$

$$M_y(\omega, k_{\parallel}, \phi) = \frac{k_1}{2k_0} \sin \phi \text{Im} \left( -\frac{(r_{sp} - r_{ps}) e^{2ik_z d}}{k_z} \right) \hbar$$

For evanescent waves ($k_{\parallel} > k_0$), $k_z = i |k_z|$ is purely imaginary which simplifies the above expressions:

$$M_x(\omega, k_{\parallel}, \phi) = \frac{k_1}{2k_0 |k_z|} \cos \phi \text{Re} \left( -\left( r_{sp} - r_{ps} \right) \right) \hbar$$

$$M_y(\omega, k_{\parallel}, \phi) = \frac{k_1}{2k_0 |k_z|} \sin \phi \text{Re} \left( -\left( r_{sp} - r_{ps} \right) \right) \hbar$$

For evanescent waves carrying large momentum $k_{\parallel} \gg k_0$ which leads to $|k_z| \approx k_{\parallel}$, the above expressions further simplify to:

$$M_x(\omega, k_{\parallel} \gg k_0, \phi) = (\sin \phi) \hbar, \quad M_y(\omega, k_{\parallel} \gg k_0, \phi) = (-\cos \phi) \hbar$$

### II. ROTATIONAL DYNAMICS OF THE PARTICLE IN IMPERFECT VACUUM

We consider a potential experiment where a particle is levitated in the near-field of doped InSb plate inside a vacuum chamber and the magnetic field along x axis is switched on at time $t = 0$. The particle at temperature $T_p \neq T_e$ experiences a lateral Casimir torque $M_z$ which causes an angular acceleration about x axis. As the particle’s angular velocity ($\Omega$) increases, there is also an additional damping torque from the residual air molecules inside the vacuum chamber. The damping torque opposes the angular velocity and it can be described as [6, 7]:

$$M_{\text{damp}} = -\frac{\Omega p_{\text{gas}} \pi (2R)^4}{11.976} \sqrt{\frac{2m_{\text{gas}}}{k_BT_e}} = -\gamma_{\text{damp}} \Omega$$

where $R$ is the radius of the nanoparticle, $m_{\text{gas}} = 4.8 \times 10^{-26}$ kg is the average mass of air molecule, and $p_{\text{gas}}$ is the air pressure. Using the particle’s moment of inertia $I_x = \frac{2}{5} m_{\text{pg}} R^2$, the evolution of its angular velocity follows the following stochastic equation derived using Brownian theory [8]:

$$d\Omega = \frac{M_x}{I_x} dt - \frac{\gamma_{\text{damp}}}{I_x} \Omega dt + \sqrt{\frac{2\gamma_{\text{damp}} k_BT_e}{I_x^2}} dW$$

where $dW$ is a normally distributed random number of mean $\langle dW \rangle = 0$ and standard deviation $\langle dW^2 \rangle = dt$ and $dt$ is the time step much smaller than the relaxation timescale $\mathcal{O}(I_x/\gamma_{\text{damp}})$. The term multiplying $dW$, also known as fluctuation–dissipation theorem (FDT), indicates that the strength of the fluctuations is related to the dissipation rate.
The above equation is simulated using Euler Maruyama method over a large number of trajectories [8]. In the absence of gyrotropy-induced lateral torque ($M_x = 0$), the specific form of FDT ensures that the average rotational energy of the particle given by $\frac{1}{2}I_x\omega^2$ is equal to $k_B T_x/2$ at equilibrium with the environment at temperature $T_x$ (equipartition law). At equilibrium, the average angular velocity $\langle \Omega \rangle = 0$ and the standard deviation $\sqrt{\langle \Omega^2 \rangle} = k_B T_x/I_x$. For AgBr and NaCl nanoparticles in an environment at $T_x = 300K$ (considered in the main text), the typical standard deviation is $\sqrt{\langle \Omega^2 \rangle} \approx 10^{7}$ rad/s.

In presence of lateral nonequilibrium Casimir torque ($M_x \neq 0$), the steady-state angular velocity is $\Omega_{ss} = M_x/\gamma_{damp}$ ignoring the fluctuating noise. It is straightforward to numerically verify that the fluctuating noise can be ignored if $\Omega_{ss} \gg 10^{7}$ rad/s. For realistic vacuum chambers of gas pressure $10^{-5}$ torr and lateral nonequilibrium torque $M_x \gtrsim 10^{-27}$ Nm attained in the near-field of InSb slab, we find $\Omega_{ss} \gg 10^{4}$ rad/s. For smaller values of torque away from the slab ($M_x < 10^{-27}$ Nm), in general, full numerical simulations including the fluctuating thermal noise are required for calculating the steady-state mean angular velocity. For predictions related to experiments involving levitated particles, both shot noise of the laser and the additional thermal noise can be considered in the above equation to obtain the steady-state mean angular velocities.

**Time taken to reach steady state:** Figure 3 in the main text reveals the rotational steady state angular velocities $\Omega_{ss} \gtrsim 10^{6}$ rad/s for AgBr and NaCl particles of radius $R = 200 \text{nm}$ in a vacuum chamber of $p_{gas} = 10^{-5}$ torr. For the above parameters, the time constant $I_x/\gamma_{damp}$ is of the order of minutes for AgBr ($\sim 140s.$) and NaCl ($\sim 48s.$) particles. As the magnetic field of 1T is turned on at $t = 0$, the particles will reach these steady state rotational velocities in few minutes.

**Angular velocity dependence of the torque:** We note that, in the above equation, the lateral Casimir torque $M_x$ is derived for a non-rotating particle. The effect of the particle’s rotational velocity $\Omega$ on the magnitude of this torque is negligible as long as its rotational velocity is much smaller than the emission frequencies ($\Omega \ll \omega$). For our situation, $\omega \sim 10^{11}$ rad/s while $\Omega_{ss} \sim 10^{7}$ rad/s and hence ignoring the dependence of $M_x$ on $\Omega$ is justified. Nonetheless, we derive $M_x(\Omega)$ below and prove this point. We follow the derivation similar to that of ref. [2] for the calculation of torque on rotating particles. The torque originating from the particle’s dipole moment fluctuations is calculated in the laboratory frame. For a particle rotating at angular velocity $\Omega$ about $x$ axis, the fluctuating dipole moments in the lab frame $p^i_{d} \xi$ are related to the fluctuating dipole moments in the rotating frame $p^i_{d} \xi'$ (FDT is well-defined in the rotating frame [2]) as:

\[
p^y_{d} = \frac{1}{2} [p^\parallel_{d y} e^{-i\omega t} + p^\parallel_{d y} e^{i\omega t} + p^{\ast \parallel}_{d y} e^{i\omega t} + p^{\ast \parallel}_{d y} e^{-i\omega t} + ip^{\parallel}_{d y} e^{-i\omega t} - ip^{\parallel}_{d y} e^{i\omega t} + ip^{\ast \parallel}_{d y} e^{i\omega t} - ip^{\ast \parallel}_{d y} e^{-i\omega t}]
\]

\[
p^z_{d} = \frac{1}{2} [-ip^{\parallel}_{d y} e^{-i\omega t} + ip^{\parallel}_{d y} e^{i\omega t} - ip^{\ast \parallel}_{d y} e^{i\omega t} + ip^{\ast \parallel}_{d y} e^{-i\omega t} + p^{\parallel}_{d y} e^{-i\omega t} + p^{\ast \parallel}_{d y} e^{i\omega t} + p^{\ast \parallel}_{d y} e^{-i\omega t} + p^{\parallel}_{d y} e^{i\omega t}]
\]

\[
p^x_{d} = p^{\parallel \ast}_{d x} e^{i\omega t} + p^{\ast \parallel}_{d x} e^{i\omega t}
\]

where $\omega = \omega \pm \Omega$ and both positive and negative frequencies are considered together such that the final integration is performed only over positive frequencies ($\int_{0}^{\infty} i\omega/2\pi$). The fluctuating dipole moments $p^{\parallel}_{d y}$ satisfy the FDTs above and are used to calculate the resulting torque. This calculation also requires induced electric fields which are obtained using the Green’s function $E_{j}^{(ind)} = G_{j k y} p^{\parallel}_{d y} e^{-i\omega t}$ for $\omega m \in [\omega, \omega, \omega_\pm]$ and its complex conjugate.

The calculation of torque originating from the electric field fluctuations requires the electric fields in the rotating frame of the particle. For the particle rotating at angular velocity $\Omega$, the field fluctuation $E^i_{\xi'}$ in the rotating frame are:

\[
E^y_{\xi'} = \frac{1}{2} [E^\parallel_{y} e^{-i\omega t} + E^{\ast \parallel}_{y} e^{i\omega t} + E^{\parallel}_{y} e^{i\omega t} + E^{\ast \parallel}_{y} e^{-i\omega t} - iE_{y} e^{-i\omega t} + iE^{\ast}_{y} e^{i\omega t} - iE_{y} e^{i\omega t} + iE^{\ast}_{y} e^{-i\omega t}]
\]

\[
E^z_{\xi'} = \frac{1}{2} [iE^{\parallel}_{y} e^{-i\omega t} - iE^{\ast \parallel}_{y} e^{i\omega t} + iE^{\parallel}_{y} e^{i\omega t} - iE^{\ast \parallel}_{y} e^{-i\omega t} + E_{y} e^{-i\omega t} + E^{\ast}_{y} e^{i\omega t} + E_{y} e^{i\omega t} + E^{\ast}_{y} e^{-i\omega t}]
\]

\[
E^x_{\xi'} = E^{\parallel \ast}_{y} e^{-i\omega t} + E^{\ast \parallel}_{y} e^{i\omega t}
\]

Using the induced dipole moments in the rotating frame, $p^i_{d} e^{i\omega t}$, the torque due to electric field fluctuations can be obtained. After some straightforward algebra, we get the following torque due to the reflected part of the Green’s function:

\[
M^x = \frac{e_0 \Theta_{\xi'}}{\omega} \left[ \text{Im}(\alpha_{\omega+} + \alpha_{\omega_+}) \Re(G^{G}_{y\xi,\omega} - G^{G}_{y\xi,\omega+}) + \text{Im}(G^G + G^G_{zz}) \text{Im}(\alpha_{\omega+} - \alpha_{\omega+}) \right]
\]

\[
M^y = \frac{e_0 \Theta_{\xi'}}{\omega} \left[ \text{Im}(G^{G}_{zz,\omega} - G^{G}_{zz,\omega+}) + \text{Im}(G^{G}_{y\xi,\omega} - G^{G}_{y\xi,\omega+}) - \Re(G^{G}_{y\xi,\omega} - G^{G}_{y\xi,\omega+}) - \Re(G^{G}_{y\xi,\omega} - G^{G}_{y\xi,\omega+}) \right]
\]
where $G^t = \omega^2 \mu_0 G$ is used for simplifying the expressions. The subscripts indicate the frequencies at which the related terms are to be evaluated. The required expressions for $G^t$ are:

$$G^t_{yz,\omega} = G^t_{zy,\omega} = \omega^2 \mu_0 \int \frac{k_{||}dk_{||}d\phi}{(2\pi)^2} \left[ \frac{2\omega^3}{3\pi\epsilon_0 c^3} \right] r_{pp} k_{||} k_z$$

$$G^t_{yy,\omega} = \omega^2 \mu_0 \int \frac{k_{||}dk_{||}d\phi}{(2\pi)^2} \left[ \frac{2\omega^3}{3\pi\epsilon_0 c^3} \right] r_{pp} k_{||} k_z$$

$$G^t_{zz,\omega} = \omega^2 \mu_0 \int \frac{k_{||}dk_{||}d\phi}{(2\pi)^2} \left[ \frac{2\omega^3}{3\pi\epsilon_0 c^3} \right] r_{pp} k_{||} k_z$$

The torque because of the vacuum part of the Green’s function in Eq. 4 (indicating direct interaction with vacuum half-space) is:

$$M^v_{x} = \frac{\epsilon_0 \Theta_T}{\omega} \text{Im}(\alpha_{\omega} - \alpha_{\omega \pm}) \frac{2\omega^3}{3\pi\epsilon_0 c^3} \text{Im}(\alpha_{\omega} - \alpha_{\omega \pm}) \Theta_T$$

$$M^v_{p} = \frac{\epsilon_0 \Theta_T}{\omega} \text{Im}(\alpha_{\omega}) \frac{2\omega^3}{3\pi\epsilon_0 c^3} \text{Im}(\alpha_{\omega}) \Theta_T$$

In the following, we use the above expressions to compute the lateral Casimir torque for the case of AgBr and NaCl particles considered in the main text.

As explained in the main text, we focus on two cases of AgBr and NaCl nanoparticles of radius $R = 200$nm in the near-field of doped InSb slab in a magnetic field $B = 1T$ along $x$ axis of the geometry. The particles experience oppositely directed lateral nonequilibrium Casimir torque and hence rotate with opposite angular velocities. Figure 1 demonstrates the dependence of the fluctuations-induced torque on the angular velocity of the particle. For this demonstration, we assumed both particles to be at surface-to-surface distance $d_s = 0.1\mu$m. from the slab surface and at temperature $T_p = 400$K. The temperature of the surrounding environment is $T_s = 300$K. Intuitively, it follows from the above torque expressions containing terms such as $\omega \pm = \omega \pm \Omega$ that the angular velocity will alter the magnitude of the torque only when it is comparable to the emission frequencies which lie in the THz range. This is evident from Fig.1 where the torque is constant for rotation velocities less than $\Omega = 10^{10}$rad/s. For particles reaching the rotation speeds beyond these values, we should use the above angular-velocity-dependent torque expressions for calculations. However, since the damping torque of the imperfect vacuum chamber balances the lateral Casimir torque at smaller rotation speeds in the MHz to GHz range, it suffices to use the torque expressions derived for steady particles. We also note that at rotation speeds beyond 10GHz where the effect of the rotation speed on the magnitude of the torque is noticeable, the particle may disintegrate because of the centrifugal stress. These effects depend on the ultimate tensile strength of the material, and must be taken into account at these high rotational velocities [7, 9].
