Studies of the X(3872) at Belle II

Elisabetta Prencipe
Justus-Liebig-University of Giessen, DE

The X(3872) is one of the most puzzling resonances ever observed. First seen by the Belle Collaboration in 2003, it solicited the effort of a hundred of experimental physicists and dozens of theorists, who nowadays are trying yet to shed light on the nature of this peculiar resonant state. It was seen in several decay modes and different production mechanisms, and confirmed by several experiments, so it is well established, and recently is addressed as the $\chi_{c1}(3872)$. Here we report about a re-discovery of the X(3872) with early Belle II data, and discuss plans for future measurements once the full integrated planned luminosity will be achieved by Belle II.

PACS numbers:

I. INTRODUCTION

The so-called X(3872) is an exotic resonant state that does not fit into potential models [1]. It was observed for the first time by the Belle Collaboration in the $B^\pm \rightarrow J/\psi\pi^+\pi^-K^\pm$ decay channels [2], by analyzing the $J/\psi\pi^+\pi^-$ invariant mass. This is one of the most cited articles ever published by Belle, updated later in 2011 [3]. Several experiments published on that [4-14], also in different production mechanisms and other decay modes [15-20]. Nowadays the X(3872) is well established, and its interpretation is still puzzling because its quantum numbers do not fit into the potential models.

II. STATE OF THE ART

The LHCb experiment definitively established that the X(3872) has $J^{PC} = 1^{++}$ [21], excluding in this way some hypotheses about its interpretation. The X(3872) can be unluckily interpreted as a standard charmonium state, due to its narrow width and strong isospin violation. The most suitable and preferred interpretations are nowadays charm molecule or tetraquark, but yet other hypotheses cannot be ruled out. In fact, among the possible explanations are those interpreting the X(3872) as a hybrid state where the gluon field contributes to its quantum numbers, or a glueball without any valence quarks at all. A mixture of these explanations is also possible.

The measurement of the X(3872) width could actually constrain theoretical models. The best value that Belle could measure as an upper limit (UL) at 90% confidence level (c.l.) was 1.2 MeV [3]. No conventional hadron is expected to have such a narrow width in the charmonium spectrum. However, recently LHCb pushed further the investigation of the X(3872) width, in B decays [7] or inclusively [8], always in the $J/\psi\pi^+\pi^-$ final state, but using different data sets. By performing an analysis of the X(3872), in the assumption of a Breit-Wigner (BW) parameterization of its lineshape, LHCb established that the X(3872) width is equal to 1.39 MeV [8]. The reason of performing a simple BW fit is that it neglects potential distortions. A precise measurement of the X(3872) lineshape could help elucidate its nature. LHCb then used also a Flatté model, and the extremely challenging width value of 220 keV was measured [22]. The LHCb results favour the interpretation of this state as a quasi-bound $D^0\bar{D}^{*0}$ molecule. Further studies are ongoing.

Both LHCb and Belle analyzed the invariant mass system of $J/\psi\pi^+\pi^-$ in B decays, for the width measurement. The conclusion reported by the LHCb analyses [14, 22] is that at the actual status of the art of this search there is no way to distinguish the Flatté from the BW model.

The logic question could be whether exists or not a decay channel that could be more sensitive to the X(3872) width measurement, and if an experiment exists, which can distinguish between different lineshape parameterizations. In other words, understanding the lineshape of the X(3872) plays a fundamental role in disclosing its nature.

A leading role in undersanding the nature of the X(3872) is played by the analysis of the $X(3872) \rightarrow D^0\bar{D}^{*0}$, which was started at Belle, but only 50 events were fitted over 657 fb$^{-1}$ data [15].

The analysis of the X(3872) in prompt production at FNAL and LHC showed interesting results:

- production rate at Tevatron is too large by orders of magnitude for a X(3872) to be a weakly-bound charm molecule [23, 24].
- re-scattering effects could introduce additional interactions between D mesons in the final state, therefore the X(3872) production rate could enhance.
- re-scattering could be significant if the relative momenta of the D mesons are small, and at large transverse momenta. Therefore, measuring the $p_T$-dependence of the X(3872) production rate could give insights about the validity of the charm-meson molecule hypothesis.
- CMS has observed copious X(3872) produced in prompt processes rather than B mesons (only 26% in B decays) [25]: the predicted $p_T$-dependence of the X(3872) is actually larger than the measured...
rate, but fairly modeled. In addition, recent observation of the X(3872) in $B_c \rightarrow X(3872)\phi$ decays at CMS suggests another laboratory for studying its properties [26].

LHCb recently scrutinized the nature of the X(3872) by studying its multiplicity dependent relative suppression compared to a conventional charmonium state, i.e. $\psi(2S)$. In the hypothesis of the X(3872) being a hadronic molecule, its radius should be large at the order of 10 fm, while in the hypothesis of a compact tetraquark it is supposed to be 1 fm [27]. If one consider the decay of the X(3872) to $D^0\bar{D}^{*0}$ mesons, the difference between the X(3872) and its decay products is found to be equal to 0.1 MeV/$c^2$. LHCb has found that the X(3872) prompt ratio decreases with the multiplicity [28], which means a stronger suppression of X(3872) over $\psi(2S)$ is observed. This argument is used against the charm molecule interpretation [29].

The Belle experiment has also given a remarkable contribution in trying to understand the properties of the X(3872), to better constrain theoretical models. In fact, it was measured:

- $\Delta M$, defined as the X(3872) mass difference in B charged and B neutral decays. It is evaluated to be $(-0.69 \pm 0.97 \pm 0.19)$ MeV/$c^2$, which is compatible with zero. This is against the quark-antiquark model.

- $R(X)$, defined as the ratio of the branching ratio of the charged and neutral B meson decays, where the X(3872) was observed. It was measured to be $(0.50 \pm 0.14 \pm 0.04)$. In the molecular model, it should range in $[0.06,0.29]$.

- search for charged partners, which gave no positive outcome in the decays $B^0 \rightarrow K^-\pi^+\pi^0J/\psi$ and $B^+ \rightarrow K^+\pi^-\pi^0J/\psi$.

- search for $B^{0,+} \rightarrow D^0\bar{D}^{*0}K^{0,+}$. The branching ratio of these 2 decay modes is found identical, within statistical error, then $R(X)$ here is compatible with 1. Evidence for the X(3872) → $D^0\bar{D}^{*0}$ has been found at Belle.

The analysis of the X(3872) → $D^0\bar{D}^{*0}$ is extremely interesting, since it shows sensitivity to the X(3872) width measurement. In fact, the difference between the X(3872) mass and that of its decay products in this case would be 7.05 MeV/$c^2$ ($D^0\bar{D}^{*0}$) and 0.1 MeV/$c^2$ ($D^0\bar{D}^{0*}$). In order to perform this analysis, and experiment with good photon reconstruction is required.

III. THE BELLE II EXPERIMENT

The Belle II experiment is an asymmetric $e^+e^-$ collider, collecting data mostly at the center of mass energy of the $\Upsilon(4S)$, which decays to $BB$ pairs. Spectroscopy analysis through B decays, or in the continuum, or via initial state radiation (ISR) are possible at B factories. So far Belle II collected 239 fb$^{-1}$ data in roughly one year of data taking, which corresponds to the integrated luminosity that the old Belle experiment collected in 4 years. The Belle II experiment can be considered as a major upgrade of the Belle experiment, and it is located at the same site, at KEKB (Tsukuba, Japan). The Belle II experiment is also not able to discriminate. Indeed LHCb in the hypothesis of Flatté parameterization, published the Flatté and the BW parameterization, which so far is also not able to discriminate. Indeed LHCb in the hypothesis of Flatté parameterization, published the impressive value of 220 keV for the X(3872) width [22]. The decay channel that will be under investigation in Belle II is $B \rightarrow D^0\bar{D}^{*0}K$ decay channel, is 189 keV (see Fig. 2).

Further studies are ongoing, considering different models for the X(3827) lineshape, to understand if Belle II will be able in early future to discriminate between, e.g. the Flatté and the BW parameterization, which so far is also not able to discriminate. Indeed LHCb in the hypothesis of Flatté parameterization, published the impressive value of 220 keV for the X(3872) width [22]. The decay channel that will be under investigation in Belle II for the purpose of the measurement of the X(3872) width is $X(3872) \rightarrow D^0\bar{D}^{*0}$. The reason is that to constrain $D^{0s} \rightarrow D^0\pi^0$ is a strong assumption, being unknown the pole position of the X(3872). In this case one makes the assumption that the X(3872) pole is above the $D^0\bar{D}^{*0}$ threshold, for which we have got

IV. CHARMONIUM SPECTROSCOPY AT BELLE II

Spectroscopy analysis through B decays, or in the continuum, or via initial state radiation (ISR) are possible at Belle II. The analysis of the X(3872) is a hot topic anal-
no confirmation so far. This assumption would exclude a priori a possible solution. By analyzing $X(3872) \rightarrow D^0 \bar{D}^0 \pi^0$ all possibilities remain open.

V. ANALYSIS OF THE $X(3872) \rightarrow J/\psi \pi^+ \pi^-$ AT BELLE II

With 62.8 fb$^{-1}$ re-processed Belle II data it was possible to study $X(3872) \rightarrow J/\psi \pi^+ \pi^-$ in $B$ decays, and confirm the former Belle result. The analysis was conducted by analyzing the $B^{+0} \rightarrow J/\psi \pi^+ \pi^- K^{+,0}$ channels. As control sample, the analysis of the $\psi(2S) \rightarrow J/\psi \pi^+ \pi^-$ was performed. Particle identification was applied to leptons and pions involved in the decay channel under exam, and a standard mass window selection around the $J/\psi$ and $K_S^0$ masses is applied. $J/\psi$ is reconstructed to leptons ($e, \mu$), then mass constrained.

Useful kinematic variables to study are $M_{bc}$ (beam-constrained mass) and $\Delta E$ (energy difference), defined as $M_{bc} = \sqrt{(E_{beam}^2/c^4 - |p_B/c|^2)}$ and $\Delta E = E_{beam} - E_B$, respectively. The continuum suppression is guaranteed by the condition $R_2 < 0.4$, where $R_2$ represents the Fox-Wolfram momentum of the second order, normalized to the zero order. The result of the unbinned maximum likelihood fit is reported in Fig. 3. The study of the control sample reveals good agreement with the PDG value.

With the statistics available for this study almost an observation of the $X(3872)$ is provided (4.6 $\sigma$ significance). The signal is efficiently reconstructed; 19.1% reconstruction efficiency is quoted on the charged $B$ channel. This preliminary analysis on early Belle II data reveals an excellent agreement with the old Belle analysis [3], with improvement in term of reconstruction efficiency, and subsequently fitted events.

VI. CONCLUSION

The Belle II experiment is performing good, and so far collected 239 fb$^{-1}$ data. Preliminary results on 62.8 fb$^{-1}$ data show the first re-discovery of the $X(3872)$. We are looking forward to collect the whole data set at the c.m. energy of the $\Upsilon(4S)$, and repeat this interesting analysis in all possible decay modes at Belle II. A plan to combine Belle and Belle II data for the investigation of the $X(3872) \rightarrow D^0 \bar{D}^0$ has been already approved.
