We discuss the character of states near the Fermi level in Mn doped GaAs, as revealed by a survey of dc transport and optical studies over a wide range of Mn concentrations. A thermally activated valence band contribution to dc transport, a mid-infrared peak at energy $\hbar \omega \approx 200$ meV in the ac conductivity, and the hot photoluminescence spectra indicate the presence of an impurity band in low doped ($\ll$1% Mn) insulating GaAs:Mn materials. Consistent with the implications of this picture, both the impurity band ionization energy inferred from the dc transport and the position of the mid-infrared peak move to lower energies and the peak broadens with increasing Mn concentration. In metallic materials with $> 2\%$ doping, no traces of Mn-related activated contribution can be identified in dc-transport, suggesting that the impurity band has merged with the valence band. No discrepancies with this perception are found when analyzing optical measurements in the high-doped GaAs:Mn. A higher energy ($\hbar \omega \approx 250$ meV) mid-infrared feature which appears in the metallic samples is associated with inter-valence band transitions. Its red-shift with increased doping can be interpreted as a consequence of increased screening which narrows the localized-state valence-band tails and weakens higher energy transition amplitudes. Our examination of the dc and ac transport characteristics of GaAs:Mn is accompanied by comparisons with its shallow acceptor counterparts, confirming the disordered valence band picture of high-doped metallic GaAs:Mn material.

PACS numbers: 75.47.-m

I. INTRODUCTION

GaAs is an intermediate band-gap III-V semiconductor, with $E_g = 1.5$ eV at low temperatures, in which an isolated Mn impurity substituting for Ga functions as an acceptor with an impurity binding energy of intermediate strength, $E_a^0 = 0.11$ eV.1,2,3,4,5 Beyond a critical Mn concentration, Mn doped GaAs exhibits a phase transition to a state in which the Mn impurity levels overlap sufficiently strongly that the ground state is metallic, i.e., that states at the Fermi level are not bound to a single or a group of Mn atoms but are delocalized across the system.2,4 In the metallic regime Mn can, like a shallow acceptor (C, Be, Mg, Zn, e.g.), provide delocalized holes with a low-temperature density comparable to Mn density, $N_{\text{Mn}}^{\text{doped}}$ (x = 1% Mn-doping corresponds to $N_{\text{Mn}} = 2.2 \times 10^{20}$ cm$^{-3}$ in GaAs:Mn.) The transition to the metallic state occurs at larger doping in GaAs when doped with Mn than when doped with shallow acceptors. Experimentally the transition appears to occur between $N_{\text{Mn}} \approx 1 \times 10^{20}$ cm$^{-3}$ and $5 \times 10^{20}$ cm$^{-3}$, as compared to the $\sim 10^{18}$ cm$^{-3}$ critical density for the shallow acceptors in GaAs.6

The hole binding potential of an isolated substitutional Mn impurity is composed of long-range Coulomb, short-ranged central-cell, and $sp - d$ kinetic-exchange potentials.2,4 Because of the kinetic-exchange and central cell interactions, Mn acceptors are more localized than shallow acceptors. A crude estimate of the critical metal-insulator transition density can be obtained with a short-range potential model, using the experimental binding energy and assuming an effective mass of valence band holes, $m^* = 0.5 m_e$. This model implies an isolated acceptor level with effective Bohr radius $a_0 = (\hbar^2/2m^*E_a^0)^{1/2} = 10 \AA$. The radius $a_0$ then equals the Mn impurity spacing scale $N_{\text{Mn}}^{-1/3}$ at $N_{\text{Mn}} \approx \ldots$
Fermi level resides inside a narrow impurity band (assuming some compensation) separated from the valence band by an energy gap of a magnitude close to the impurity binding energy. In this regime strong electronic correlations are an essential element of the physics and a single-particle picture has limited utility. Well into the metallic state, on the other hand, the impurities are sufficiently close together, and the various potentials which contribute to the binding energy of an isolated impurity are sufficiently screened, that the system is best viewed as an imperfect crystal with disorder-broadened and shifted host Bloch bands. In this regime, electronic correlations are usually less strong and a single-particle picture often suffices.

Although neither picture is very helpful for describing the physics in the crossover regime which spans some finite range of dopings, the notion of the impurity band on the lower doping side from the crossover and of the disordered host band on the higher doping side from the crossover still have a clear qualitative meaning. The former implies that there is a deep minimum in the density-of-states between separate impurity and host band states. In the latter case the impurity band and the host band merge into one inseparable band whose tail may still contain localized states depending on the carrier concentration and disorder. We note that terms overlapping and merging impurity and valence bands describe the same basic physics in GaAs:Mn. This is because the Mn acceptor states span several unit cells even in the very dilute limit and many unit cells as the impurity band broadens with increasing doping. The localized and the delocalized Bloch states then have a similarly mixed As-Ga-Mn spd-character. This applies to systems on either side of the metal-insulator transition. We also point out that for randomly distributed Mn dopants in GaAs the impurity band is not properly modeled by assuming a Bloch-like, effective mass character.

The impurity band and the disordered valence band regimes are schematically illustrated in Fig. 1. In Sections II to IV of this article we discuss a survey of previously published dc and ac transport data and new dc measurements of GaAs:Mn materials grown in the Nottingham and Prague molecular-beam-epitaxy (MBE) systems spanning a wide range of Mn concentrations. Our comprehensive study complements previous investigations of specific narrower doping regions. It shows that the picture of the crossover from the impurity band at low dopings to the disordered valence band at high dopings, illustrated in Fig. 1 and generally accepted for the shallow acceptor counterparts to GaAs:Mn, applies well to the intermediate extrinsic GaAs:Mn. The perception of merged impurity and valence bands in highly Mn-doped metallic GaAs is now also firmly established in the microscopic theory community and provides a qualitative, and often a semiquantitative description of micromagnetic and magnetotransport characteristics of bulk and microstructured (Ga,Mn)As ferromagnets.
Our article, which we believe further establishes the valence band nature of the Fermi level states in metallic GaAs:Mn, is timely as the topic is still not fully settled. Several recent interpretations of optical measurements in GaAs:Mn have favored the impurity band picture of highly doped metallic materials. These works provided additional motivation for the analysis presented here, for which we conclude that the optical data in the high-doped GaAs:Mn are not inconsistent with the disordered valence band nature of states near the Fermi energy, inferred from dc-transport.

Finally, before moving to the technical sections let us remark that comparisons between samples with different nominal Mn concentrations have to be treated with caution. The Mn doping parameter should only be considered as an approximate guideline for qualitative discussion of doping trends. This applies namely to epitaxial materials with higher Mn concentrations in which nominal, growth-rate controlled Mn doping parameter can deviate significantly from the amount of Mn impurities incorporated in the acceptor-like Ga-substitutional positions. Moreover, the partial densities of various types of Mn impurities and of other compensating and structural defects can vary significantly depending on applied growth conditions.

II. LOW-DOPED INSULATING GaAs : Mn SYSTEMS WITH IMPURITY BANDS

Narrow impurity bands are expected and have been clearly observed in Mn doped GaAs samples with carrier densities much lower than the metal-insulator transition density, for example in equilibrium grown bulk materials with \( N_{\text{Mn}} = 10^{17} - 10^{19} \text{ cm}^{-3} \).\(^{23,24,25}\) The energy gap between the impurity band and the valence band, \( E_a \), can be measured by studying the temperature dependence of longitudinal and Hall conductivities, which show activated behavior because of thermal excitation of holes from the impurity band to the much more conductive valence band.\(^{22,27,28}\) Examples of these measurements are shown in Figs. 2-4.

The activation energy decreases with increasing Mn density, following roughly the form:

\[
E_a = E_a^0 [1 - (N_{\text{Mn}}/N_{\text{Mn}}^c)]^{1/3}.
\]

The lowering of impurity binding energies at larger \( N_{\text{Mn}} \), which is expected to scale with the mean impurity separation as expressed in Eq. (1), is apparent already in the equilibrium grown bulk materials with \( N_{\text{Mn}} = 10^{17} - 10^{19} \text{ cm}^{-3} \). The trend continues in epitaxially grown (at 400 °C) GaAs:Mn with \( N_{\text{Mn}} \approx 1 \times 10^{19} \) and \( 6 \times 10^{19} \text{ cm}^{-3} \).\(^{29}\) When this trend is extrapolated using Eq. (1) it places the disappearance of the gap at Mn dopings of \( \approx 1\% \). Note that this estimate has a large scatter depending also on whether all Mn or only ionized Mn impurities are considered when fitting the data by Eq. (1) (see Figs. 2 and 3).

For \( N_{\text{Mn}} \approx 1 \times 10^{19} \text{ cm}^{-3} \) \( (x \approx 0.06\%) \), \( E_a \approx 70 \text{ meV} \) and a sharp crossover from impurity band hopping conduction to activated valence band conduction is observed at \( T \approx 80 - 100 \text{ K} \) (see Figs. 3 and 4). Near the crossover, \( N_{\text{Mn}}/p \sim 10^3 - 10^5 \) where \( p \) is the valence-band hole density, consistent with the much higher mobility of valence band holes compared to impurity band holes in this regime for which the distinction is clearly still valid and useful. (Note that in the bulk equilibrium-grown samples the temperature at which the crossover occurs appears to be very sensitive to the detailed disorder configuration at this Mn doping level, with some samples being strongly insulating and others showing signatures of filamentary conducting channels.\(^{26,27,29}\))

For the \( N_{\text{Mn}} \approx 6 \times 10^{19} \text{ cm}^{-3} \) \( (x \approx 0.3\%) \) epitaxial sample\(^{26}\) \( E_a \approx 50 \text{ meV} \) and the crossover from impurity band conduction to activated valence band conduction can still be identified at \( T \approx 140 \text{ K} \) (see Fig. 3). The notion of the very low mobility impurity band separated from a Bloch valence band starts to blur at this doping as the \( N_{\text{Mn}}/p \) ratio near the conduction-type crossover is only about 100.

In the dilute limit where the system has a narrow insulating impurity band, the ac conductivity is expected to show a broad mid-infrared feature due to impurity band to valence band transitions, peaked at energy be-
between $E_a$ and $2E_a$.\textsuperscript{26-31} Lower energy peak positions correspond to shallow acceptors with weakly bound impurity states composed of a narrow range of valence band wavevector Fourier components. The peak near $2E_a$ and a line shape $\sigma(\hbar\omega) \sim E_a^{1/2}(\hbar\omega - E_a)^{3/2}/(\hbar\omega)^3$ correspond to a short-range impurity potential for which a larger interval of valence band states contributes to the transition amplitude. Consistent with these expectations a peak at $\hbar\omega \approx 200$ meV is observed in the weakly doped ($N_{Mn} \sim 10^{17}$ cm$^{-3}$) GaAs:Mn samples (see Fig. 3).\textsuperscript{1,26,32} At $N_{Mn} \sim 10^{19}$ cm$^{-3}$, the peak is slightly red shifted ($\hbar\omega \approx 180$ meV) and significantly broadened.\textsuperscript{26} Both the red-shifting and the broadening are expected consequences of increasing overlap between acceptor levels.

In the dilute doping disorder free limit, hot photoluminescence (HPL) can provide another optical spectroscopy tool, when combined with a reliable measure of the heavy hole kinetic energy at the valence band to conduction band excitation energy, to measure the position of a narrow impurity band with respect to the top of the valence band.\textsuperscript{33} For a GaAs:Mn sample doped with $\sim 10^{17}$ cm$^{-3}$ of Mn, a HPL spectrum has been obtained (see also Fig. 9) that is consistent with excitations from the valence band to the conduction band followed by transitions of the hot electrons (before their energy is dissipated in the conduction band) into the impurity level. An edge can be identified in the spectrum which corresponds to an impurity level $\sim 120 \pm 10$ meV above the top of the valence band, in agreement with the above dc and infrared ac transport data and other experiments.\textsuperscript{1,2,3,4,5}

We conclude that in the low doping regime, the temperature-dependent dc transport data and the ac conductivity data consistently indicate the presence of an impurity band and the decrease in $E_a$ as doping brings the impurity band closer to the valence band. Note that the activated dc transport marker of the impurity band is common to both the intermediate Mn acceptor and the shallow acceptors in GaAs.\textsuperscript{11} The infrared ac conductivity feature, on the other hand, appears to be a more subtle and less reliable tool for identifying the presence of the impurity band. To our knowledge, there are no reports...
of the impurity band transitions in infrared ac measurements for GaAs doped with shallow acceptors. In these systems, even when weakly doped and still insulating, the reported infrared ac conductivity peaks are ascribed to inter-valence-band transitions due to non-zero thermally activated or metallic hole densities in the valence band\textsuperscript{34-36}. The inter-valence-band transitions in metallic GaAs:Mn will be analyzed in detail in Section IV.

III. IMPURITY-BAND TO DISORDERED-VALENCE-BAND CROSSOVER AND HIGH-DOPED METALLIC GaAs : Mn

At higher Mn doping around \( \approx 1\% \), the conductivity curves can no longer be separated into an impurity-band dominated contribution at low temperatures and an activated valence-band dominated contribution at higher temperatures, even though the samples are still insulators (see Fig. 6). In metallic materials with \( x > 2\% \), no signatures of Mn-related hole activation is observed when temperature is swept to values as high as 500 K, \( i.e. \) to \( T \approx E_0^s/2 \), and before the intrinsic conductance due to activation across the GaAs band-gap takes over (see Fig. 6).

For completeness, we show in Fig. 7 temperature-dependent resistivity curves for a set of metallic, annealed high conductivity ferromagnetic samples, which, within experimental uncertainty of 20\%, show no compensation and conductivities up to \( \approx 900 \, \Omega^{-1} \, \text{cm}^{-1} \). We note here that the high-doped metallic GaAs:Mn samples show only weak temperature-dependence of the conductivity associated with the onset of ferromagnetism and that the conductivity varies slowly with Mn composition in the metallic samples but changes dramatically in going from 1 to 1.5\% Mn in these samples. We also note that no marked dependence of the hole density on temperature is observed for metallic samples\textsuperscript{8}.

The absence of the impurity band in high-doped GaAs:Mn is further evident by comparisons with other related materials (see Fig. 8) for which the disordered valence band picture has not been questioned. The narrower-gap InAs:Mn counterparts to GaAs:Mn, \( e.g. \) in which Mn acts as a shallower acceptor have similarly low magnitudes and similar temperature-dependence of the conductivity\textsuperscript{37,38,39}. Comparably low conductivities (or mobilities) are also found in epitaxially grown GaAs doped with \( \sim 10^{20} \, \text{cm}^{-3} \) of the shallow non-magnetic acceptor Mg\textsuperscript{40}. Note that the highest mobilities in p-type GaAs with the doping levels \( \sim 10^{20} - 10^{21} \, \text{cm}^{-3} \) are achieved with Zn and C and these are only \( 5 - 10 \times \) larger as compared to GaAs:Mn (see Fig. 8)\textsuperscript{41,42}.

We also remark that valence band calculations treating disorder in the Born approximation overestimate the experimental dc conductivities of metallic GaAs:Mn by less than a factor of ten\textsuperscript{43,44} and that any sizable discrepancy is removed by exact-diagonalization calculations\textsuperscript{45} (see also Fig. 12) which account for strong disorder and localization effects. This provides another confirmation for the plausibility of the disordered valence band picture.

![Graph showing conductivity and resistivity changes](image-url)

FIG. 6: Comparison of longitudinal conductivities (upper panel) and resistivities (lower panel) of 0.07\% and 1\% doped insulating paramagnetic GaAs:Mn, and 2.5\% and 7\% Mn doped ferromagnetic (\( T_c \) approximately 40 K and 170 K, resp.) metallic GaAs:Mn grown in the Prague MBE system with As\textsubscript{4} flux. The 0.07\% doped material was grown at 530\textdegree, the other materials were grown by low-temperature MBE (240-200\textdegree). The 0.07\% doped sample shows clear GaAs:Mn impurity band – valence band activation at low temperatures, impurity band exhaustion, and the onset of activated transport over GaAs band gap at high temperatures. The 2.5\% and 7\% doped samples show only weak conductance variations associated with the onset of ferromagnetism until the activated transport over GaAs band gap takes over.

Similarities between GaAs doped with Mn and with shallow acceptors, Zn in particular, are also found in the experimental HPL spectra, as shown in Fig. 9\textsuperscript{24,33}.
While for doping levels $\sim 10^{17} \text{ cm}^{-3}$ a sharp onset of the luminescence at frequencies corresponding to transitions into the impurity bands in these materials is clearly detected, the HPL impurity band marker is not apparent at high dopings. For the metallic GaAs:Zn with $N_{\text{Zn}} \approx 10^{19} \text{ cm}^{-3}$ and for the 4% doped GaAs:Mn, the spectra show only broad luminescence with no clear indication of an onset but rather a featureless decrease continuing out towards the laser energy.

The first infrared ac conductivity measurements in high-doped GaAs:Mn, reported in Refs. 48, 49, were inconclusive. Only two samples were compared in both of these works, with approximately 3% and 5% nominal Mn-doping. The absence of a clear mid-infrared peak in the 5% material in Ref. 48 and the re-entrant insulating behavior of the higher doped sample in Ref. 49 suggest that the growth at this early stage had not been optimized so as to minimize the formation of unintentional defects and to achieve appreciable growth reproducibility.

The more recent and more systematic infrared absorption measurements for an insulating sample close to the metal-insulator transition and for a set of metallic highly doped GaAs:Mn materials are shown in Fig. 10. The ac conductivity of the 1.7% doped insulating sample...
is featureless in the mid-infrared region. This can be interpreted as a natural continuation of the trend, started in the low doped samples, in which the impurity band moves closer to the valence band and broadens with increasing doping, becoming eventually undetectable in the ac conductivity spectra. Note that the disappearance of the impurity band transitions can in principle result also from a strong compensation. A strong unintentional compensation in epitaxial GaAs:Mn at the ~ 1% doping level is not typical, however. The 1.7% doped sample from Ref. 50 has a room temperature conductivity in the dc limit of about 5 Ω⁻¹·cm⁻¹, which presumably drops to a much lower value at 5 K. This is consistent with the σ(T) dependence of the insulating 1% sample from the series of epitaxial materials in Fig. 4 which show no signatures of strong compensation over the entire range of doping from 0.07-7%.

A new mid-infrared feature emerges in the metallic > 2% doped samples at frequencies, hω ∼ 250 meV, and is then red-shifted by ≈ 80 meV as the doping is further increased to approximately 7% without showing a marked broadening (see Fig. 10, 23,32). The association of this peak to an impurity band is implausible because of (i) the absence of the activated dc-transport counterpart in the high-doped metallic samples, (ii) the blue-shift of this mid-infrared feature with respect to the impurity band transition peak in the N_Mn ≈ 10¹⁹ cm⁻³ sample, (iii) the appearance of the peak at frequency above 2E₀, and (iv) the absence of a marked broadening of the peak with increased doping. In the following section we argue that this peak in the infrared conductivity of metallic GaAs:Mn is consistent with the picture of merged impurity and valence bands in these materials.

IV. RED SHIFT OF THE MID-INFRARED ABSORPTION ABOVE INSULATOR-TO-METAL TRANSITION

A mid-infrared peak has been observed in metallic GaAs heavily doped (∼ 10¹⁹ - 10²⁰ cm⁻³) with shallow hydrogenic carbon acceptors and explained in terms of inter-valence-band transitions between heavy holes and light holes. This peak blue-shifts with increasing doping as the Fermi energy moves further into the valence and, consequently, the transitions move to higher energies (see Fig. 11). The conclusions of previous sections suggest that the mid-infrared peaks in the metallic GaAs:Mn materials should be of a qualitatively similar origin. The red-shift seen in GaAs:Mn can be understood by recalling that while GaAs doped with ∼ 10¹⁹ - 10²⁰ cm⁻³ C is already far on the metallic side, GaAs doped with ∼ 10²⁰ - 10²¹ cm⁻³ of Mn is still close to the metal-insulator transition.

The merging of the impurity band and the valence band near the transition is illustrated schematically in Fig. 1. For metallic GaAs:Mn close to the metal-insulator transition, states in the band tail can still be expected to remain localized and spread out in energy (see lower panels in Fig. 1). The red shift of the inter-valence-band transitions can result from an increased metallic with increasing doping. At lower doping the abundance of localized states in the broad valence band tail enables transitions which take spectral weight from the low frequency

![Figure 10](Image)

**FIG. 10:** Infrared absorption measurements of GaAs:Mn. Top panel: comparison of GaAs, low-doped GaAs:Mn and high-doped as-grown GaAs:Mn materials at 292 K. Middle panel: Comparison of high-doped as-grown and annealed GaAs:Mn samples at 7 K. Bottom panel: Absorption measurements for the 5.2% as-grown GaAs:Mn below and above the ferromagnetic transition temperature. From Refs. 23,32,50.
region and provide a channel for higher-energy transitions. As doping increases, the valence band tail narrows because of increased screening. The inter-valence-band absorption peak then red-shifts as the low-frequency part of the spectrum adds spectral weight.

A support for this picture can be found in finite-size exact-diagonalization calculations reported in Ref. 45 which were intended to address the influence of strong disorder on the ac conductivity in metallic GaAs:Mn close to the metal insulator transition. In these numerical data, shown in Fig. 12, the mid-infrared feature is shifted to lower energies in the higher hole density more conductive system. In both experimental and numerical calculation cases, the red-shift of the peaks is accompanied by an increase of the dc conductivity. In experiment, this correlation is observed both by comparing different samples and, in a given sample, over the entire range of temperatures that was studied, below and above the ferromagnetic transition temperature (see Fig. 10).

We emphasize that no general practical sum rule exists for the low-frequency part of the ac conductivity and that a Drude fit of the spectra near the dc limit would tend to strongly overestimate band effective masses as the metal-insulator transition is approached. In GaAs:Mn in particular, most of the experimental ac conductivity curves in Fig. 10 as well as the numerical simulations in Fig. 12 do not show a maximum at zero frequency23,32,45,50 which makes the Drude fitting questionable.

Finally we point out that the absolute conductance values of the mid-infrared conductivity peak found experimentally in metallic GaAs:Mn materials, which are expected to be relatively insensitive to disorder, agree with the values predicted theoretically by the inter-valence-band transition calculations. This includes both the calculations treating disorder within the Born approximation, which overestimate the dc conductivity, and the exact-diagonalization studies shown in Fig. 12 which account for strong disorder and localization effects.

FIG. 11: Infrared absorption measurements of metallic GaAs:C. From Ref. 36. Inset illustrates the origin of the blue shift of the mid-infrared peak in these highly metallic systems.

FIG. 12: Exact diagonalization study showing the red shift of the valence band mid-infrared peak for the Kohn-Luttinger model assuming lower hole concentration and stronger disorder due to larger number of compensating defects (dots) and higher hole density and weaker disorder (rectangles). Lines are 10th-order polynomial fits to the numerical data to guide the eye.
In summary, a number of dc transport and optical measurements have been performed during the past four decades to elucidate the nature of states near the Fermi level in GaAs:Mn in the insulating and metallic regimes. A detail examination of these studies, complemented with new dc transport data and comparisons with shallow acceptor counterparts to GaAs:Mn, show that impurity band markers are consistently seen in the insulating low-doped materials. Similar consistency is found when analyzing experiments in the high-doped metallic materials, in this case strongly favoring the disordered valence band picture. Our conclusions support the established theoretical description of GaAs:Mn based on a variety of different \textit{ab initio} and phenomenological approaches which explain many experimental magnetic and magnetotransport properties of these dilute moment ferromagnetic semiconductors.
