**Background:** Synaptotagmin-1, a Ca$^{2+}$ sensor of neuronal exocytosis, interacts with the anionic phospholipid phosphatidylinositol 4,5-bisphosphate (PIP$_2$).

**Results:** Microscale thermophoresis shows that PIP$_2$ binding to the polybasic patch of synaptotagmin-1 increases the Ca$^{2+}$ affinity by $>$40-fold.

**Conclusion:** PIP$_2$ and Ca$^{2+}$ binding to synaptotagmin-1 is strongly cooperative.

**Significance:** Understanding the interplay between Ca$^{2+}$, synaptotagmin-1, and PIP$_2$ is crucial for our understanding of neurotransmitter release.

---

Synaptotagmin-1 is the main Ca$^{2+}$ sensor of neuronal exocytosis. It binds to both Ca$^{2+}$ and the anionic phospholipid phosphatidylinositol 4,5-bisphosphate (PIP$_2$), but the precise cooperativity of this binding is still poorly understood. Here, we used microscale thermophoresis to quantify the cooperative binding of PIP$_2$ and Ca$^{2+}$ to synaptotagmin-1. We found that PIP$_2$ bound to the well conserved polybasic patch of the C2B domain with an apparent dissociation constant of $\sim$20 μM. PIP$_2$ binding reduced the apparent dissociation constant for Ca$^{2+}$ from $\sim$250 to $<5$ μM. Thus, our data show that PIP$_2$ makes synaptotagmin-1 $>$40-fold more sensitive to Ca$^{2+}$. This interplay between Ca$^{2+}$, synaptotagmin-1, and PIP$_2$ is crucial for neurotransmitter release.

---

In the synaptic terminal, neurotransmitter release is mediated by fusion of synaptic vesicles with the plasma membrane. Fusion is triggered by a sudden increase in the cytoplasmic Ca$^{2+}$ concentration in response to membrane depolarization. The protein synaptotagmin-1 (together with synaptotagmin-2 and synaptotagmin-9) is the main Ca$^{2+}$ sensor of the fast phase of neuronal exocytosis (reviewed in Ref. 1). Synaptotagmin-1 contains a single transmembrane domain close to the N terminus, which anchors the protein to synaptic vesicles. The transmembrane domain is connected by a 61-residue unstructured nus, which anchors the protein to synaptic vesicles. The transmembrane domain contains a single transmembrane domain close to the N terminus of neuronal exocytosis (reviewed in Ref. 1). Synaptotagmin-1 (together with synaptotagmin-2 and synaptotagmin-9) is the main Ca$^{2+}$ sensor of the fast phase of neuronal exocytosis. It binds to both Ca$^{2+}$ and the anionic phospholipid phosphatidylinositol 4,5-bisphosphate (PIP$_2$), but the precise cooperativity of this binding is still poorly understood. Here, we used microscale thermophoresis to quantify the cooperative binding of PIP$_2$ and Ca$^{2+}$ to synaptotagmin-1. We found that PIP$_2$ bound to the well conserved polybasic patch of the C2B domain with an apparent dissociation constant of $\sim$20 μM. PIP$_2$ binding reduced the apparent dissociation constant for Ca$^{2+}$ from $\sim$250 to $<5$ μM. Thus, our data show that PIP$_2$ makes synaptotagmin-1 $>$40-fold more sensitive to Ca$^{2+}$. This interplay between Ca$^{2+}$, synaptotagmin-1, and PIP$_2$ is crucial for neurotransmitter release.

---

Ca$^{2+}$ binding to synaptotagmin-1, originally demonstrated by equilibrium dialysis using native protein (2), has been characterized by isothermal titration calorimetry (3) and NMR (4–6) using a soluble fragment containing both C2 domains (C2AB fragment, residues 97–421). The C2A domain binds to three Ca$^{2+}$ ions with affinities ranging from 50 μM to 10 μM. The C2B domain binds two Ca$^{2+}$ ions, both with $\sim$200 μM affinity.

In the presence of Ca$^{2+}$, the C2 domains of synaptotagmin-1 also bind to membranes containing anionic phospholipids, with little specificity for the phospholipid species (3, 6–14). Interestingly, binding already occurs at Ca$^{2+}$ concentrations well below the Ca$^{2+}$ affinity of free synaptotagmin-1. Here, anionic phospholipid headgroups complement the Ca$^{2+}$-binding sites, increasing the affinity of C2AB for Ca$^{2+}$ to $\sim$5–100 μM (3, 6–8, 11, 13). In the absence of Ca$^{2+}$, a conserved polybasic lysine patch located on the C2B domain can also bind to anionic lipids, and this binding is strongly preferential for the polyanionic phospholipid phosphatidylinositol 4,5-bisphosphate (PIP$_2$)$^3$ (3, 9–14). Binding of PIP$_2$ to the polybasic patch might increase the Ca$^{2+}$ affinity (12), although this is still controversial (3) and has hitherto not been characterized in detail.

Experimentally, measuring synaptotagmin-1 binding to PIP$_2$ and/or Ca$^{2+}$ is not trivial. Isothermal titration calorimetry and NMR require high (100 μM to 1 mM) concentrations of protein (3–5). Therefore, high affinities well below these concentrations cannot be accurately determined with these approaches. Binding of synaptotagmin to PIP$_2$ is often inferred from binding of the C2 domains to artificial membranes containing a defined fraction of PIP$_2$ (e.g. by FRET (3), pulldown assays (11, 13), or density flotations (3, 12)). However, it is difficult to quantitatively distinguish Ca$^{2+}$ from PIP$_2$ binding with these approaches. We have recently shown (10) that Ca$^{2+}$ binding to synaptotagmin-1 can be directly measured with a new technique called microscale thermophoresis (MST) (15, 16). MST is based on the principle that molecules move along a tempera-

ture gradient in a capillary (the Soret effect). Upon binding to Ca\textsuperscript{2+}/H\textsubscript{11001} or PIP\textsubscript{2}, the surface properties of synaptotagmin-1 change, resulting in an altered thermophoretic behavior. In this study, we applied MST to study PIP\textsubscript{2} and Ca\textsuperscript{2+}/H\textsubscript{11001} cooperative binding to synaptotagmin-1.

**EXPERIMENTAL PROCEDURES**

The C2AB fragment of synaptotagmin-1 (rat sequence, residues 97–421) was expressed in *Escherichia coli* and purified as described (3, 10). The single cysteine mutant (C278S/S342C) was labeled with Alexa Fluor 488-maleimide (Invitrogen) as described (3, 10). Liposomes were prepared by extrusion of rehydrated lipid films through 100-nm pores (polycarbonate membranes, Avestin) (17). All lipids were from Avanti Polar Lipids. MST was measured with 50 nM fluorescently labeled C2AB in 20 mM HEPES, 150 mM KCl, and 2.5 mg/ml BSA at pH 7.4. The samples were added to hydrophobic capillaries (NanoTemper Technologies), and MST was measured using a NanoTemper Monolith NT.015 system (25% light-emitting diode, 40% IR laser power). The label-free (tryptophan) experiments were performed with 1 μM wild-type C2AB, no BSA, and the NanoTemper Monolith NT.LabelFree instrument (80% UV light-emitting diode, 40% IR laser power). The MST curves were fitted with simple Michaelis-Menten kinetics to obtain the apparent dissociation constant for Ca\textsuperscript{2+} (K\textsubscript{Ca}) or PIP\textsubscript{2} (K\textsubscript{PIP2}). For Ca\textsuperscript{2+} binding, \( T = A - B/(K_{Ca} + [Ca^{2+}]) \), where \( T \) is the percentage of fluorescence after heating, [Ca\textsuperscript{2+}] is the total calcium concentration in the capillary, and \( A \) and \( B \) are conversion factors for the thermophoresis.

**RESULTS**

We performed MST measurements on the Alexa Fluor 488-labeled C2AB fragment of synaptotagmin-1 (residues 97–421). With this technique, a glass capillary is filled with a dilute protein solution (50 nM). Fluorescence is then measured at a spot in the capillary that is locally heated by a focused IR laser (IR on). C2AB thermophoreses away from the heated spot, causing a local depletion and a drop in fluorescence. Ca\textsuperscript{2+} binding changes the thermophoretic properties of C2AB, resulting in a decreased thermophoresis. MST time traces of 16 different Ca\textsuperscript{2+} concentrations (ranging from 0 to 5 mM). Note that thermophoresis is reversed at high Ca\textsuperscript{2+} concentrations. C, dependence of the MST signal on the Ca\textsuperscript{2+} concentration (measured 30 s after turning on heating; data from B). The solid line is a fit with Michaelis-Menten kinetics, yielding an apparent dissociation constant of \( K_{Ca} = 221 \mu M \). No change in the MST signal was observed in the presence of Mg\textsuperscript{2+} or when a mutant impaired in Ca\textsuperscript{2+} binding was used (D178A/D230A/D232A/D309A/D363A/D365A, called C2a*b*). D, same as C but using unlabeled C2AB. MST was measured using intrinsic tryptophan fluorescence and fitted, yielding \( K_{Ca} = 206 \mu M \). Error bars indicate the range of data points obtained from at least two measurements.

**FIGURE 1. Ca\textsuperscript{2+} binding to C2AB measured by MST.** A, principle of MST. A capillary containing 50 nM Alexa Fluor 488-labeled C2AB is locally heated by a focused IR laser (IR on). C2AB thermophoreses away from the heated spot, causing a local depletion and a drop in fluorescence. Ca\textsuperscript{2+} binding changes the thermophoretic properties of C2AB, resulting in a decreased thermophoresis. B, MST time traces of 16 different Ca\textsuperscript{2+} concentrations (ranging from 0 to 5 mM). Note that thermophoresis is reduced at high Ca\textsuperscript{2+} concentrations. C, dependence of the MST signal on the Ca\textsuperscript{2+} concentration (measured 30 s after turning on heating; data from B). The solid line is a fit with Michaelis-Menten kinetics, yielding an apparent dissociation constant of \( K_{Ca} = 221 \mu M \). No change in the MST signal was observed in the presence of Mg\textsuperscript{2+} or when a mutant impaired in Ca\textsuperscript{2+} binding was used (D178A/D230A/D232A/D309A/D363A/D365A, called C2a*b*). D, same as C but using unlabeled C2AB. MST was measured using intrinsic tryptophan fluorescence and fitted, yielding \( K_{Ca} = 206 \mu M \). Cooperativity of Ca\(^{2+}\) and PIP\(_2\) Binding to Synaptotagmin-1

![Graphs](image)

**FIGURE 2.** Ca\(^{2+}\) dependence of MST signal of C2AB in presence of PIP\(_2\)-containing liposomes. A, Ca\(^{2+}\) binding of the C2AB fragment in the presence of 1,2-dioleoyl-sn-glycero-3-phosphatidylcholine (PC)-containing liposomes (2.5 mM total lipid concentration) yielded an apparent dissociation constant of \(K_{Ca} = 226.7 \pm 50.7 \mu M\) (black). However, when 10% of the 1,2-dioleoyl-sn-glycero-3-phosphatidylcholine-containing liposomes contained 5 mol % PIP\(_2\), the affinity increased by \(\sim 5\)-fold to \(K_{Ca} = 46.0 \pm 5.9 \mu M\) (red). B, Liposome binding as a function of the fraction of PIP\(_2\)-containing liposomes. In all cases, the total lipid concentration was 2.5 mM, but the fraction of liposomes containing 5 mol % PIP\(_2\) varied. In the absence of Ca\(^{2+}\), C2AB bound to the PIP\(_2\) membranes with \(K_{Ca} = 36.2 \pm 7.4\%\) (or 45.3 \(\mu M\) PIP\(_2\); cyan). In the presence of 50 \(\mu M\) Ca\(^{2+}\), the affinity increased by 4-fold to \(K_{Ca} = 10.6 \pm 2.3\%\) (or 13.3 \(\mu M\) PIP\(_2\); green). C, Binding of C2AB to liposomes composed of a 5:2:1:1 molar ratio of brain isolated phosphatidylincholine, phosphatidylethanolamine, phosphatidylserine, and cholesterol. C2AB did not bind to liposomes lacking PIP\(_2\) regardless of the presence (green) or absence (blue) of 50 \(\mu M\) Ca\(^{2+}\). In contrast, C2AB bound to liposomes containing 1 mol % PIP\(_2\) already in the absence of Ca\(^{2+}\) (red). Similar to B, 50 \(\mu M\) Ca\(^{2+}\) increased the binding affinity (\(K_{Ca} = 50.9 \pm 20.0 \mu M\) total lipid concentration; black). D, Ca\(^{2+}\) binding curve of C2AB in the presence (red) and absence (blue) of 20 \(\mu M\) PIP\(_2\). 1 mM Mg\(^{2+}\) was present to suppress potentially unspecific Ca\(^{2+}\)-PIP\(_2\) interactions. Error bars indicate the range of data points obtained from at least two measurements.

Curves, this simplification may affect the quality of the fit. However, the overall quality of the data did not warrant fitting with a more sophisticated binding model. Thus, we could not differentiate between the different calcium-binding sites, and we report only the apparent dissociation constant (\(K_{Ca}\)).

C2AB bound to Ca\(^{2+}\) with \(K_{Ca} = 221 \pm 23 \mu M\) (n = 3). Control experiments with Mg\(^{2+}\) or a mutant with disrupted Ca\(^{2+}\) binding (D178A/D230A/D232A/D309A/D363A/D365A, called C2a\(_b^\)\(_b^\)) (3, 10) showed that the change in the MST signal was indeed due to binding of Ca\(^{2+}\) ions to the established binding sites in the C2 domains. Furthermore, the MST measurements were not affected by the presence of the dye because a similar binding constant of \(K_{Ca} = 206 \pm 40 \mu M\) was obtained with the unlabeled C2AB fragment using the intrinsic tryptophan fluorescence as the readout (C2AB has three tryptophans) (Fig. 1D). We then set out to study the cooperativity of Ca\(^{2+}\) and PIP\(_2\) binding.

No apparent change in the Ca\(^{2+}\)-dependent thermophoretic behavior of C2AB was observed in the presence of liposomes composed of pure 1,2-dioleoyl-sn-glycero-3-phosphatidylcho-line (2.5 mM total lipid concentration; \(K_{Ca} = 226.7 \pm 50.7 \mu M\)) (Fig. 2A). In contrast, the apparent affinity for Ca\(^{2+}\) increased by \(\sim 5\)-fold when only 10% of these liposomes were replaced with a liposome population composed of 95% 1,2-dioleoyl-sn-glycero-3-phosphatidylcholine and 5% PIP\(_2\) (\(K_{Ca} = 46.0 \pm 5.9 \mu M\)). Accordingly, the addition of 50 \(\mu M\) Ca\(^{2+}\) (well below the \(K_{Ca}\) of C2AB) resulted in \(\sim 4\)-fold stronger binding to PIP\(_2\)-containing liposomes (from \(K_{Ca} = 45.3 \pm 9.25 \mu M\) to \(K_{Ca} = 13.3 \pm 2.9 \mu M\); Fig. 2B). 50 \(\mu M\) Ca\(^{2+}\) also increased C2AB binding to liposomes containing a more physiological lipid composition (phosphatidylcholine/phosphatidylethanolamine/phosphatidylserine/cholesterol at a molar ratio of 5:2:1:1) but only if 1 mol % PIP\(_2\) was present (Fig. 2C). Thus, synaptotagmin-1 binds to anionic membranes and Ca\(^{2+}\) in a cooperative manner, as reported previously (3, 6–13). We performed a set of experiments with water-solubilized PIP\(_2\) to further characterize this cooperativity.

One of the main advantages of MST compared with alternative techniques for measuring Ca\(^{2+}\) binding is the low concentration of protein that is required: measurements could be carried out with C2AB concentrations as low as 50 nm, which is 3–4 orders of magnitude below that reported for isothermal titration calorimetry (3) or NMR (4–6). This low concentration allowed us to measure PIP\(_2\) binding by adding PIP\(_2\) directly to the capillary (Fig. 2D). Even PIP\(_2\) isolated from porcine brain with long fatty acid acyl chains (dominant species C18:0 and C20:4) is water-soluble at concentrations up to \(\sim 9 \mu M\) and does poorly form micelles because of its high anionic charge (18).
Strikingly, the affinity for Ca\(^{2+}\)/PIP\(_2\) binding increased by 15-fold in the presence of 20 \(\mu\)M PIP\(_2\) (from \(K_{Ca} = 265.2 \pm 27.4 \mu\)M to 17.7 \(\pm\) 0.7 \(\mu\)M) (Fig. 2D). In this experiment, an excess of 1 mM Mg\(^{2+}\) was present to suppress potential nonspecific interactions of Ca\(^{2+}\) with PIP\(_2\) or C2AB. At higher PIP\(_2\) concentrations, the Ca\(^{2+}\) affinity increased even further (to >40-fold; \(K_{Ca} = 3.3 \pm 1.3 \mu\)M at 40 – 80 \(\mu\)M PIP\(_2\) compared with 221 \(\pm\) 23 \(\mu\)M without PIP\(_2\)) (Fig. 3, A–C). Accordingly, the addition of Ca\(^{2+}\) progressively increased the binding affinity of C2AB for PIP\(_2\) (from \(K_{Ca} = 20 \pm 5 \mu\)M without Ca\(^{2+}\) to <2 \(\mu\)M at >20 \(\mu\)M Ca\(^{2+}\)). This cooperativity is not specific for PIP\(_2\) or the length of the acyl chains because another phosphoinositide (20 \(\mu\)M phosphatidylinositol 3,4,5-trisphosphate) or short-chain PIP\(_2\) (20 \(\mu\)M 1,2-dioctanoyl-sn-glycero-3-phosphatidylglycerol) also increased the apparent Ca\(^{2+}\) affinity (\(K_{Ca} = 11 \pm 5 \text{ and } 8 \pm 5 \mu\)M, respectively).

PIP\(_2\) binding required the well conserved polybasic patch that is located on the C2B domain because removal of two lysines from this patch (K326A/K327A, the so-called KAKA mutant (12)) (Fig. 3, D–F) almost completely abolished PIP\(_2\)-dependent MST changes, even at very high Ca\(^{2+}\) concentrations. Accordingly, the apparent affinity for Ca\(^{2+}\) was increased by only ~3-fold in the presence of 80 \(\mu\)M PIP\(_2\) (from \(K_{Ca} = 195 \pm 35 \mu\)M to 61 \(\pm\) 11 \(\mu\)M). Thus, we could detect only PIP\(_2\) binding to the polybasic patch and did not observe PIP\(_2\) binding via the Ca\(^{2+}\)-binding sites on the C2A.
Cooperativity of Ca\textsuperscript{2+} and PIP\textsubscript{2} Binding to Synaptotagmin-1

FIGURE 4. Cooperative Ca\textsuperscript{2+} and PIP\textsubscript{2} binding to C2AB. The apparent dissociation constants for Ca\textsuperscript{2+} binding (K\textsubscript{Ca}; A) and PIP\textsubscript{2} binding (K\textsubscript{PIP2}; B) were determined by MST. Wild-type C2AB (see Fig. 3, A–C) and various mutants were tested: KAKA (K326A/K327A; see Fig. 3, D–F), C2a*B (a*B; D178A/D230A/D232A), C2Ab* (Ab*; D309A/D363A/D365A), C2a*b* (a*b*; D178A/D230A/D232A/D309A/D363A/D365A), and KAKA/C2a*B (KAKA a*B). The KAKA/C2Ab* and KAKA/ C2a*b* mutants are not shown in the figure because PIP\textsubscript{2} and Ca\textsuperscript{2+} binding could not be detected with MST (see Fig. 1C). Error bars show the range of data points obtained from at least two measurements. C, conservation of the PIP\textsubscript{2}-binding sites. The crystal structure of the C2B domain (purple; Protein Data Bank code 1TJX (26)) was overlapped with that of the PIP\textsubscript{2}-bound PKC\textalpha{} C2 domain (green; code 3GPE (25)). D, all residues that stabilize the PIP\textsubscript{2} headgroup (orange) are conserved in the C2B domain (see also Ref. 25).

and C2B domains, in contrast to previous observations by us and others (3, 10–12, 14). It is likely that, for the interaction of the Ca\textsuperscript{2+}-binding pockets with the membrane, hydrophobic residues surrounding these pockets must insert into the membrane (6–8, 11, 12, 14), although we cannot exclude that PIP\textsubscript{2} binding to the Ca\textsuperscript{2+} sites is silent (i.e. does not change the MST signal). Nevertheless, the Ca\textsuperscript{2+}-binding pocket of the C2B domain does affect PIP\textsubscript{2} binding to the polybasic patch because disruption of Ca\textsuperscript{2+} binding to the C2B domain (D309A/ D363A/D365A, called C2Ab*) reduced the affinity for PIP\textsubscript{2} by ~4-fold (from K\textsubscript{PIP2} = 20.4 ± 5.2 M to 70 ± 24 M) (Fig. 4B).

We then performed MST experiments with mutants disrupted in Ca\textsuperscript{2+} binding to the C2A domain (D178A/D230A/ D232A, called C2a*B). Surprisingly, only a small and insignificant PIP\textsubscript{2}- or Ca\textsuperscript{2+}-dependent change in the MST signal of C2a*B was observed compared with the wild type (Fig. 4, A and B). Accordingly, the combination of C2a*B with the KAKA mutation did not markedly differ from the KAKA mutant with all Ca\textsuperscript{2+}-binding sites intact. Apparently, Ca\textsuperscript{2+} binding to the C2A domain does not result in a detectable change in the thermophoretic properties of the C2AB fragment. In contrast, Ca\textsuperscript{2+} binding could no longer be detected by MST upon disruption of the C2B domain. Thus, only Ca\textsuperscript{2+} binding to the C2B domain seems to change the thermophoretic properties of the C2AB fragment, indicating that the calcium-dependent changes reported above are exclusively mediated by the C2B domain. Perhaps this selectivity is related to the thermodynamically divergent modes of Ca\textsuperscript{2+} binding of synaptotagmin-1: Ca\textsuperscript{2+} binding to the C2A domain is endothermic, and that to the C2B domain is exothermic (3). Finally, Ca\textsuperscript{2+} concentrations above 100 M increased the apparent PIP\textsubscript{2} affinity of synaptotagmin-1 even when both Ca\textsuperscript{2+}-binding sites were disrupted (double mutant C2a*b*) (Fig. 4B). This indicates that Ca\textsuperscript{2+} was still able to bind to the double mutant at very high Ca\textsuperscript{2+} concentrations in the presence of PIP\textsubscript{2}, perhaps by binding directly to PIP\textsubscript{2} (19, 20).

DISCUSSION

In this work, we have shown that PIP\textsubscript{2} binds to the polybasic patch of the C2B domain of synaptotagmin-1, in agreement with earlier studies (10–14, 21). PIP\textsubscript{2} binding to the polybasic patch increases the apparent affinity of the C2B domain for Ca\textsuperscript{2+} by >40-fold. Conversely, Ca\textsuperscript{2+} binding to the C2B domain increases the affinity for PIP\textsubscript{2} by >10-fold. Cooperative PIP\textsubscript{2} and Ca\textsuperscript{2+} binding to synaptotagmin-1 has been observed previously (12). This cooperativity is probably not caused by complementation of the Ca\textsuperscript{2+}-binding sites, as suggested earlier by us and others (3, 6–8), because the polybasic patch and...
Cooperativity of Ca\(^{2+}\) and PIP\(_2\) Binding to Synaptotagmin-1

the Ca\(^{2+}\)-binding sites are located quite far apart (Fig. 4C). Instead, PIP\(_2\) may interact in a structurally less defined manner with the polybasic patch and other solvent-exposed basic residues (9, 12), and this may increase the Ca\(^{2+}\) affinity simply by charge screening. Alternatively, the polybasic patch may form a structurally defined complex with PIP\(_2\) similar to the C2 domains of rabphilin-3A and PKC\(\alpha\) (22–25). In fact, cooperative PIP\(_2\) and Ca\(^{2+}\) binding has been observed for these C2 domains (22–24), very similar to our observations for the C2B domain. Moreover, the crystal structure of the C2B domain (26) can be superimposed with that of the PIP\(_2\)-bound C2 domain of PKC\(\alpha\) (25), rendering it likely that PIP\(_2\) binds to the C2AB fragment of synaptotagmin-1 in a similar manner (Fig. 4, C and D). Thus, it is conceivable that such PIP\(_2\) binding increases the Ca\(^{2+}\) affinity via a conformational change. However, how PIP\(_2\) and Ca\(^{2+}\) precisely bind in a cooperative manner to synaptotagmin-1 remains to be elucidated.

Together, we conclude that PIP\(_2\) binding to the polybasic patch of synaptotagmin-1 dramatically increases the Ca\(^{2+}\) sensitivity. As discussed previously (12), this explains the reduced release probability of the KAKA mutant in hippocampal neurons (12, 27) and in Drosophila (28). It also explains why in vivo already 10 \(\mu\)M Ca\(^{2+}\) is sufficient for physiological release of neurotransmitters in the calyx of Held (29). PIP\(_2\) modulation of synaptotagmin-1 may well be of major physiological relevance when considering that PIP\(_2\) can be superimposed with that of the PIP\(_2\)-bound C2 domain of PKC\(\alpha\) (11), synaptotagmin-1 remains to be elucidated.

Finally, our work demonstrates the value of MST for measuring molecular interactions. Although we were unable to detect Ca\(^{2+}\) binding to the C2A domain under our conditions, MST can be extremely sensitive and allows for monitoring medium and high affinity interactions with only picomoles of material. MST has the potential to complement the limited set of techniques available to measure Ca\(^{2+}\) and PIP\(_2\) binding to proteins under equilibrium conditions such as isothermal titration calorimetry and NMR.
