We study the structure of star-forming galaxies at \( z \sim 2 \) in a Great Observatories Origins Deep Survey North field selected as star-forming BzK (sBzK) galaxies down to \( K_{AB} < 24.0 \) mag. Among 1029 sBzK galaxies, 551 galaxies (54\%) show a single component in the Advanced Camera for Survey (ACS)/F850LP image obtained with the Hubble Space Telescope; the rest show multiple components. We fit the single-component sBzK galaxies with the single Sérsic profile using the ACS/F850LP image and find that a majority of them (64\%) show a Sérsic index of \( n = 0.5-2.5 \), indicating that they have a disk-like structure. The resulting effective radii typically range from 1.0 to 3.0 kpc in the rest-frame UV wavelength. After correcting the effective radii to those in the rest-frame optical wavelength, we find that the single-component sBzK galaxies are located in the region where the local and \( z \sim 1 \) disk galaxies are distributed in the stellar-mass–size diagram, suggesting comparable surface stellar-mass density between the sBzK and \( z \sim 0-1 \) disk galaxies. All these properties suggest that the single-component sBzK galaxies are progenitors of the present-day disk galaxies. However, by studying their intrinsic shape through comparison between the observed distribution of apparent axial ratios and the distribution for triaxial models with axes \( A > B > C \), we find that the mean \( B/A \) ratio is \( 0.61^{+0.05}_{-0.08} \) and disk thickness \( C/A \) is \( 0.28^{+0.03}_{-0.04} \). This indicates that the single-component sBzK galaxies at \( z \sim 2 \) have a bar-like or oval shape rather than a round disk shape. The shape seems to resemble a bar/oval structure that forms through bar instability; if this is the case, the intrinsic shape may give us a clue to understand dynamical evolution of baryonic matter in a dark matter halo.

**Key words:** galaxies: evolution – galaxies: formation – galaxies: high-redshift – galaxies: structure

**Online-only material:** color figures
BM/BX and sBzK galaxies. They derived a velocity structure using the Hα emission line and found that about one-third of their sample galaxies are rotation-dominated disks which follow a velocity–size relation similar to local disk galaxies. However, these galaxies show larger velocity dispersion than local disks, maybe suggesting a thicker disk. These observational results seem to suggest that star-forming galaxies at \( z \sim 2 \) are disk galaxies with a thicker disk. However, no study of the intrinsic shape of these galaxies has been established yet.

The intrinsic structure of galaxies is related to the apparent axial ratio \((b/a)\) or ellipticity \((1−b/a)\) of galaxies. In the local universe, it is found that elliptical and disk galaxies have different observed axial ratio distributions. The distribution for local elliptical galaxies peaks at \((b/a) \sim 0.8\) and decreases to zero at \((b/a) = 0.2\), whereas disk galaxies show a rather flat distribution in the range of \((b/a) \sim 0.2−0.8\) (e.g., Lambas et al. 1992; Padilla & Strauss 2008; Underborn & Ryden 2008). In this paper, we constrain the intrinsic three-dimensional structure of sBzK galaxies at \( z \sim 2 \) from their observed axial ratios in order to investigate whether they indeed have a disk structure or not.

This paper is organized as follows. Section 2 describes the optical-to-mid-infrared data sources used in this study. In Section 3, we construct a sample of sBzK galaxies and derive their photometric redshifts and stellar masses. The morphological analysis is described in Section 4. Then we examine the intrinsic shape of the sBzK galaxies from their distributions of apparent axial ratios in Section 5. The possible origin and evolution of the intrinsic structure are discussed in Section 6. Conclusions are presented in Section 7. Throughout this paper, we use the AB magnitude system (Oke et al. 1983) and assume a standard ΛCDM cosmology with parameters of \( \Omega_m = 0.3, \Omega_\Lambda = 0.7, \) and \( H_0 = 70 \text{ km s}^{-1} \text{ Mpc}^{-1} \).

2. DATA SOURCES

We used the publicly available images in \( U, B, V, R, I_c, \) and \( z' \) bands in the Great Observatories Origins Deep Survey North (GOODS-N) field (Capak et al. 2004). The \( U\)-band image was obtained with the Mosaïc prime focus camera on the Kitt Peak National Observatory 4 m telescope. The \( B, V, R, I_c, \) and \( z' \)-band images were obtained with Suprime-Cam attached to the Subaru telescope. Details of the data reduction can be found in Capak et al. (2004). The seeing sizes of U-, B-, V-, R-, I_c-, and \( z' \)-band images are 1.3′, 1′, 1′, 1′, 1′, and 1′, respectively and the 5σ limiting magnitudes at 3′′ diameter aperture are 26.5, 26.0, 25.7, 25.8, 25.1, and 24.8 mag, respectively.

In order to study the morphology of sBzK galaxies, we used the high-resolution image observed with Advanced Camera for Surveys (ACS) on the Hubble Space Telescope (HST). The F850LP image (hereafter referred as \( z_{850} \) image) was obtained from the HST/ACS v2.0 data products of the GOODS HST/ACS treasury program (Giavalisco et al. 2004) and covered an area of \( \sim 160 \text{ arcmin}^2 \). The pixel scale of the image is 0.03 pixel\(^{-1}\). The full width at half-maximum (FWHM) of the point-spread function (PSF) is \( \sim 0.1′′ \). The 5σ limiting magnitude of the \( z_{850} \) image is 26.5 mag at 1′′ diameter aperture.

For the near-infrared data, we used very deep and wide \( J, H, \) and \( K \)-band data obtained with the Multi-Object InfraRed Camera and Spectrograph (MOIRCS; Suzuki et al. 2008) on the Subaru telescope, i.e., MOIRCS Deep Survey (MODS; Kajisawa et al. 2006; Ichikawa et al. 2007). Four MOIRCS pointings cover \( \sim 70\% \) of the GOODS-N region (103.3 arcmin\(^2\), hereafter “wide field;” Kajisawa et al. 2009). One of the four pointings includes the Hubble Deep Field North (Williams et al. 1996) and is the deepest field of the MODS (hereafter deep field). The FWHM of the PSF is \( 0.′60 \) for the deep field and \( 0.′61 \) for the wide field. The images reach \( J = 25.3, H = 24.6, \) and \( K = 25.1 \text{ mag} (5\sigma \text{ at } 2′′ \text{ diameter aperture}) \) for the wide field and \( J = 26.0, H = 24.9, \) and \( K = 25.7 \text{ mag} \) for the deep field.

Mid-infrared images were obtained from deep observations with the Infrared Array Camera (IRAC) on the Spitzer Space Telescope (SST). We used 3.6 and 4.5 μm band images from the First (DR1) and Second Data Release (DR2) of the publicly available data provided by the SST Legacy Science program.6 The pixel scale of all images after being drizzled is 0.′60 pixel\(^{-1}\). The 5σ limiting magnitudes of the IRAC 3.6 and 4.5 μm images at 2′ diameter aperture are 25.4 and 25.3 mag, respectively.

3. SAMPLE SELECTION AND SED FITTING

In order to select star-forming galaxies at \( z \sim 2 \) using the BzK method, we first made position registrations of \( B \) and \( z' \)-band images by using the \( K \)-band image as a reference. All images were homogenized to have seeing sizes of 1′.1. Object detection was made in the \( K \)-band image with criteria of five connections above a 1.5σ minimum threshold by SExtractor version 2.5.0 (Bertin & Arnouts 1996). For each object with \( \text{MAG}_{\text{AUTO}} < 24.0 \) in \( K \) band, aperture photometry was made for \( B \) and \( z' \) bands at 1′ diameter aperture by using the dual-image mode of SExtractor, where the aperture size was found to provide the best signal-to-noise ratio (S/N) for the homogenized images.

Star-forming galaxies at \( z \sim 2 \) were selected by applying the BzK color criterion for sBzK (Daddi et al. 2004) to the \( K \)-selected galaxies down to \( K < 24.0 \text{ mag} \). Since the response functions in our system are not identical to those used by Daddi et al. (2004), we derived the color correction by convolving the empirical stellar spectra from Pickles (1998) with the response functions including the detector’s quantum efficiency and atmospheric transmission. We found that \( B − z' \) colors of stars in our system are bluer than those in Daddi et al. (2004) by about 0.05–0.4 mag depending on the spectral type, whereas our \( z' − K \) colors are 0.02 mag redder on average. In order to apply the BzK criterion consistent with Daddi et al. (2004), we applied the \( B − z' \) color correction to all objects by using the following equation:

\[
(B − z)_{\text{Daddi}} = (B − z') + 0.4.
\]

Although the offset of 0.4 mag is not valid for all colors of \( B − z \), it makes the selection criterion more secure as it is the upper limit offset. We did not correct for the \( z' − K \) colors. The original sBzK criterion, \( B + 2z \equiv (z − K) − (B − z) \geq −0.2 \), was then applied to construct the sBzK sample. Objects with \( z_{\text{spec}} < 1.4 \) or \( z_{\text{spec}} > 2.5 \) are excluded from the sample based on spectroscopic identifications by Wirth et al. (2004) and Barger et al. (2008). The resulting sample consists of 1029 sBzK galaxies.

In order to study the morphological properties, we cross-matched the sBzK galaxies with the high-resolution \( z_{850} \) image, for which the central wavelength corresponds to the rest-frame UV wavelength of \( \sim 3000 \text{ Å} \) at \( z \sim 2 \). Counterparts

**Figure 1.** Two-color $(B - z')$ vs. $(z' - K)$ diagram for sBzK galaxies in GOODS-N field. The $B - z'$ color shown here was corrected to match the filter system used by Daddi et al. (2004) (see the text for more details). Red solid circles in the left panel represent 551 single-component sBzK galaxies, while red open circles in the right panel show 478 multiple-component objects (Section 3). All objects with $K < 24.0$ mag are also shown with dots.

![Figure 2](image2.png)  
**Figure 2.** Magnitude histograms of all and single-component sBzK galaxies in $K$ band (left panel) and $z'$ band (right panel). Open histograms are for all sBzK galaxies after removing objects with $z_{\text{spec}} < 1.4$ or $z_{\text{spec}} > 2.5$, while gray shaded histograms represent the single-component sBzK galaxies.

of the sBzK galaxies in the $z_{\text{spec}}$ images are identified if they are detected above 3σ limiting magnitude (27 mag) within 0′′.72 radius centered at the positions of sBzK galaxies in the $K$-band image. This radius is twice as large as the median 1/2FWHM of the sample. The sBzK galaxies are divided into two groups: sBzK galaxies matched with only one object in the $z_{\text{spec}}$ image (hereafter single-component objects) and sBzK galaxies matched with more than one object (hereafter multiple-component objects). Five hundred and fifty-one galaxies are classified as single-component objects and 478 galaxies are multiple-component objects; 54% of the sBzK galaxies show a single structure in the $z_{\text{spec}}$ image. Figure 1 indicates that the single-component and the multiple-component sBzK galaxies show very similar distributions in the BzK diagram (left and right panels, respectively). In this paper, we concentrate our analysis on single-component objects (red circles in the left panel of Figure 1). $K$ magnitudes and $z'$ magnitudes of the single-component galaxies, which are shown in Figure 2, are distributed in the range of 20.0–24.0 mag and 21.0–26.0 mag, respectively. The distributions of all sBzK galaxies are also shown in both panels with open histograms. It is worth noting that as star-forming regions in a face-on galaxy could be seen separately in the rest-frame UV wavelength, it is possible that they are selected as a multiple-component object in this analysis. Study of structure at the rest-frame optical wavelength in the future would be helpful to see if they really have multiple components or just star-forming regions in a face-on galaxy.

The photometric redshifts and stellar masses of the single-component sBzK galaxies were obtained by spectral energy distribution (SED) fitting. SEDs of the single-component sBzK galaxies were constructed by photometry in the $U, B, V, R, I_c, z', J, H, K$, IRAC 3.6 μm, and 4.5 μm bands. For all but IRAC images, we smoothed the images to match the seeing size of $U$-band images (1′′.3) as it has the worst seeing size. Then the aperture photometry was made at 1′′.6 diameter aperture by using the dual-image mode. The total magnitudes were obtained by using the correction factor that was determined by scaling the aperture magnitude of each object to the MAG\_AUTO in the $K$-band image. For the IRAC images, we made aperture photometry without homogenizing the images at 2′′.4 diameter aperture, which maximizes the S/N. The total magnitudes were obtained by using the aperture.
correction factor determined for each band. The process of determining the aperture correction factor is identical to that used by Yuma et al. (2010). Aperture photometry at the same aperture size as done for our targets was made for artificial objects with known total magnitudes put into the IRAC images. The correction factors are $-0.62 \text{mag}$ and $-0.72 \text{mag}$ for 3.6 $\mu$m and 4.5 $\mu$m bands, respectively. The photometric redshifts of the single-component sBzK galaxies were obtained with Hyperz (Bolzonella et al. 2000). We checked the accuracy of our photometric redshift estimation using objects with available spectroscopic redshifts (Barger et al. 2008). The comparison between the photometric and the spectroscopic redshifts shows median and standard deviation of $\delta z \equiv (z_{\text{phot}} - z_{\text{spec}})/(1 + z_{\text{spec}})$ of $-0.03$ and 0.07, respectively. The histogram of the resulting photometric redshifts is shown in the left panel of Figure 3. Most of the samples have photometric redshifts between 1.3 and 2.5. Note that although we did not exclude sBzK galaxies with $z_{\text{phot}} < 1.3$ or $z_{\text{phot}} > 2.5$ from our sample, it does not affect the results. The stellar mass was obtained from SED fitting with Hyperz. We constructed model SEDs of various star-formation histories (i.e., instantaneous burst, constant star formation, or exponentially declining models) by using the Bruzual & Charlot (2003) synthesis code. A Salpeter (1955) initial mass function (IMF) with a mass range of 0.1–100 $M_\odot$ was assumed. The metallicity was fixed at solar abundance. The dust attenuation law of Calzetti et al. (2000) was adopted and the $E(B-V)$ range was taken from 0.0 to 1.0 mag with a step of 0.01 mag. The SED-fitting process was the same as that used by Yuma et al. (2010). The histogram of stellar masses is shown in the right panel of Figure 3. It is seen that most of the single-component sBzK galaxies have stellar masses of $10^9$–$10^{11} M_\odot$.

4. MORPHOLOGICAL ANALYSIS

4.1. Estimation and Accuracy of Sérsic Parameters

We determined the structural parameters of the single-component sBzK galaxies by fitting the two-dimensional light distributions in the $z_{850}$ image with a single Sérsic profile (Sérsic 1963, 1968). The Sérsic profile is expressed by $I(r) = I_e \exp[-\kappa_n((r/r_e)^{1/n} - 1)]$, where $I_e$ is the surface brightness at the effective radius $r_e$ and $\kappa_n$ is a parameter related to the Sérsic index $n$. The index $n$ determines the shape of the profile. In the local universe, an exponential profile ($n = 1$) is seen for a disk component, whereas $n \sim 4$ is representative of a spheroid component. The two-dimensional profile fitting was done by using the GALFIT version 2 (Peng et al. 2002). There are seven free parameters which are determined by $\chi^2$ minimization: central position, total magnitude, $n$, $r_e$, apparent axial ratio ($b/a$), and position angle. The Sérsic index $n$ was initially set to be $n = 1.5$. We tested the dependence of final GALFIT results on the initial Sérsic index by varying the initial $n$ from 1.0 to 4.0 and found that varying the initial Sérsic index does not affect the final fitting results ($\Delta n/n < 0.05$). Other initial guess parameters for the fit are outputs from the SExtractor. The noise for each pixel required for deriving the errors is determined from the variance maps produced during the drizzling process. The PSF used for convolving with the Sérsic model was obtained by stacking images of unsaturated stars with stellarity index larger than 0.98 and without nearby objects in the $z_{850}$ image.

Examples of GALFIT results are shown in Figure 4. We excluded objects with incredibly large errors obtained from GALFIT, which comprise about 9% of the single-component sBzK galaxies. The unreasonably large errors of some objects indicate the divergence in the fitting process. The number of remaining single-component sBzK galaxies is 499.

We carried out Monte Carlo simulations in order to examine the accuracy and reliability of the parameters derived by GALFIT. About 5000 artificial objects were generated for disks ($n = 1$) and spheroids ($n = 4$), with uniformly distributed random magnitudes (21–26 mag), random effective radii (0′01–1′00), ellipticities (0.1–1.0), and position angles (0–180°). The magnitude range was adopted so as to be the same as that of our sample. The artificial galaxies were then convolved with PSF of the $z_{850}$ image and inserted into the observed $z_{850}$ image. GALFIT was performed on the artificial objects in a manner identical to that used for the sBzK galaxies.

Figure 5 shows the resultant accuracy of the output parameters from Monte Carlo simulations with $1 \sigma$ of distributions as a function of the input $z_{850}$ magnitude. The left panel represents the accuracy of the recovered Sérsic indices. Over the whole range of magnitudes in the simulations (21–26 mag), the output $n$ distribution has a median value of $\langle n \rangle = 0.96$ with $\sigma_n = 0.68$ for the disks and $\langle n \rangle = 3.49$ with $\sigma_n = 1.34$ for the spheroids. Typical errors on $n$ obtained from GALFIT are 0.02 and 0.06 for the simulated disks and spheroids, respectively. The recovered $n$ is significantly underestimated for the objects with $n > 4$; however, it is possible to distinguish two populations by classifying objects with $n \geq 2.5$ as
spheroid-like and those with \( n < 2.5 \) as disk-like down to \( z_{850} = 24.5 \) mag. At \( z_{850} \sim 25.5 \) mag, about half of the input objects with \( n = 4 \) show output \( n \leq 2.5 \), but the fraction of the single-component sBzK galaxies fainter than 25.5 mag is very small. Nevertheless, keeping this in mind, we also examine the brighter subsample in the subsequent analysis (Section 5.3).

The right panel of Figure 5, which shows the accuracy of the recovered \( r_e \), indicates that the disk profiles are better recovered than the spheroid profiles. The effective radii of disk profiles are well recovered down to a magnitude of 26.0 mag. The typical errors in determining the effective radius are 3% for the disks and 12% for the spheroids in the magnitude range of 20.0–26.0.

4.2. Results on Sérsic Parameters

Distributions of effective radius \( (r_e) \) and Sérsic index \( (n) \) are shown in Figure 6. The effective radius is described in kpc calculated with the photometric redshift. Most of the...
Figure 5. Accuracy of the output parameters from GALFIT based on Monte Carlo simulations as a function of magnitude for the recovered median Sersic index (left panel) and median effective radius (right panel). Open circles and triangles refer to artificial objects with an exponential profile ($n = 1$) and those with a spheroid profile ($n = 4$), respectively. Error bars correspond to 1σ of the distribution.

(A color version of this figure is available in the online journal.)

Figure 6. Distributions of effective radius $r_e$ (left panel) and Sersic index $n$ (right panel). All 499 single-component sBzK galaxies are shown in the solid gray histogram, whereas those with $z_{850} < 24.5$ mag are in the open red histogram.

(A color version of this figure is available in the online journal.)

single-component sBzK galaxies show an effective radius around 1–3 kpc (Figure 6(a)), which is consistent with previous studies of star-forming galaxies at $z = 2–4$ (Overzier et al. 2010; Swinbank et al. 2010). We also show in the figure the distributions for the galaxies with $z_{850} < 24.5$ mag, which is the limiting magnitude at which the structural parameters are well recovered. It is seen that the distributions of all single-component sBzK galaxies and of those with $z_{850} < 24.5$ mag are very similar. In Figure 6(b), the distribution of derived Sersic index peaks at $n \sim 1$ for both samples. If we refer to a galaxy with $n \geq 2.5$ as a “spheroid-like” object and that with $0.5 \leq n < 2.5$ as a “disk-like” object, we find that 64% (318/499) of the single-component sBzK galaxies are disk-like objects.

In Figure 7, we plot Sersic index $n$ against effective radius $r_e$. A slight anticorrelation between the effective radii and the Sersic indices is seen; galaxies with larger size show smaller Sersic index. Such a trend can also be seen among Lyα emitters at $z = 3.1$ in the rest-frame UV wavelength (Gronwall et al. 2010). It is interesting to note that the trend is different from the correlation for early-type galaxies in the local universe, where the Sersic index increases with increasing size (Caon et al. 1993; D’Onofrio 2001; Graham & Guzman 2003; Aguerri et al. 2004; Rothberg & Joseph 2004; Aceves et al. 2006; Kormendy et al. 2009; Ascaso et al. 2011).

Figure 8 shows the effective radius against stellar mass of the single-component sBzK galaxies with $0.5 \leq n < 2.5$ and the relations for local galaxies. Since our analysis is based on the $z_{850}$ image which corresponds to the rest-frame UV wavelength ($\sim 3000$ Å) at $z \sim 2$, it is difficult to compare the results for sBzK galaxies with those for local galaxies which have been
studied in the optical wavelength. In order to make a more useful comparison, we corrected the effective radius in the rest-frame UV to that in the rest-frame optical wavelength with $r_{e, \text{opt}}/r_{e, \text{UV}} = 1.37$, the ratio of median effective radius in the rest-frame UV and optical wavelengths for star-forming galaxies (BM/BX and LBGs) at the similar redshift by Swinbank et al. (2010). The stellar masses of the local galaxies are corrected to the Salpeter IMF. It is seen from the figure that the corrected effective radius of the $z \sim 2$ sBzK galaxies slightly depends on their stellar mass; size increases with the stellar mass. Most of the single-component sBzK galaxies are distributed in the region where the local disks or $z \sim 1$ disks studied by Barden et al. (2005) are located (contours). In other words, most of the sBzK galaxies show a surface stellar-mass density comparable to the local disks, though some of them show larger surface stellar-mass densities that are more typical of local elliptical galaxies (green line; Shen et al. 2003). These results seem to suggest that most of the single-component sBzK galaxies at $z \sim 2$ already have a disk structure close to that of present-day disk galaxies.

5. DISTRIBUTION OF APPARENT AXIAL RATIO ($b/a$) AND INTRINSIC SHAPE OF THE sBzK GALAXIES

5.1. $b/a$ Distribution of the Single-component sBzK Galaxies

The peak of the Sérsic-index distribution at $n \sim 1$ suggests that most of the single-component sBzK galaxies are disk-like. The nature of $n \sim 1$ is usually interpreted as evidence for a disk galaxy. However, it is important to investigate whether they indeed have a disk shape or not. In the local universe, the intrinsic three-dimensional shape is examined statistically from the distributions of the apparent axial ratios $b/a$ (e.g., Ryden 2004; Vincent & Ryden 2005; Padilla & Strauss 2008; Unterborn & Ryden 2008). In this study, we examine the distribution of the apparent axial ratios of the single-component sBzK galaxies, and compare it with a model distribution to constrain their intrinsic shape.

The $b/a$ distribution of the single-component sBzK galaxies with $0.5 \leq n < 2.5$ is shown in Figure 9. The peak of the distribution is at $b/a \sim 0.4$. The $b/a$ distribution of the present-day disks is also shown in Figure 9 just to demonstrate the $b/a$ distribution in the case of a round disk shape. The study of a recent, very large ($\sim 303,000$) sample of disk galaxies from the Sloan Digital Sky Survey Data Release 6 (SDSS DR6) by Padilla & Strauss (2008) shows that the $b/a$ distribution of the single-component sBzK galaxies is clearly different from that for the local disks; the distribution of the sBzK galaxies is skewed toward low $b/a$ with the peak at $b/a \sim 0.4$. This implies that the single-component sBzK galaxies do not have a round disk structure.

5.2. Bias on $b/a$ Distribution

Because edge-on galaxies tend to show a greater surface brightness than face-on galaxies at the same magnitude, our sample can possibly be biased toward the edge-on galaxies at faint magnitudes. This may cause the $b/a$ distribution to artificially peak at the lower value. In order to test the selection bias in the K band, we generated 10,000 artificial objects with random inclination angles (axial ratios), uniformly distributed magnitudes (21–24 mag), and random effective radii that are comparable to the actual objects observed in the images at each magnitude bin. After being convolved with the PSF of the K-band image, the artificial objects were inserted into the K-band image and re-detected by using a process identical to that used for real galaxies. Figure 10 shows the resulting detection rate of the artificial galaxies as a function of an input axial ratio. For the artificial objects with $K_{SB} = 21–23$ mag, the detection rate is almost constant regardless of the axial ratio and is not lower than 95%. In the faintest magnitude bin (23–24 mag), the detection rate is $\sim 100\%$ at axial ratio ($b/a$) of 0.1–0.2 (edge-on) and decreases to $\sim 87\%$ at higher $b/a$ values. Though there is a decreasing trend of the detection rate with increasing $b/a$,
the detection rate remains almost constant from $b/a = 0.3$ to $b/a = 1.0$. Therefore, the selection bias is unlikely to be the cause for the peak of the $b/a$ distribution of the single-component sBzK galaxies.

We also tested this with the $z_{850}$ image. We generated 5,000 artificial objects with various magnitudes and effective radii for each model of an exponential disk and an exponential disk plus $r^{1/4}$ bulge (disk+bulge). The disk+bulge profile was constructed by assuming the bulge-to-disk ratio ($B/D$) of 0.5. The ratio of effective radii of bulge against disk is assumed to be 0.1, which is an average ratio for local galaxies in the $B$ band (de Jong 1996).

The artificial objects were analyzed in the same manner as for the sBzK galaxies, i.e., fitting with a single Sérsic profile. The comparisons between the input and the recovered axial ratios are shown in Figure 11 for disk (left panel) and disk+bulge (right panel) profiles. The axial ratios are well recovered at $z_{850} = 23$–24 mag as seen in both models. The scatter becomes larger at the fainter magnitudes, but no artificial effect which increases the number of output $b/a$ around 0.4 is seen in either the disk or disk+bulge case. Therefore, the peak of the recovered axial ratio at $b/a \sim 0.4$ seen in our sBzK sample is considered to be real.

### 5.3. Intrinsic Shape of the Single-component sBzK Galaxies

To examine the intrinsic shape of the sBzK galaxies, we employ the same method as that used for the local disk galaxies. Ryden (2004) modeled a galaxy as a triaxial ellipsoid with major axis $A$, middle axis $B$, and minor axis $C$ parameterized by two quantities: disk ellipticity ($\epsilon \equiv 1 - B/A$) and disk thickness ($C/A$). She then fitted the model with the observed distribution of apparent axis ratios. Following Ryden (2004), we adopted a model in which the disk ellipticity is assumed to have a lognormal distribution with mean $\mu (= \ln \epsilon)$ and dispersion $\sigma$, while the disk thickness has a Gaussian distribution with mean $\mu_C$ and standard deviation $\sigma_C$. These four parameters $\mu$, $\sigma$, $\mu_C$, and $\sigma_C$ give a distribution of the intrinsic shapes of galaxies. By randomly selecting an ellipticity and a disk thickness from the distribution, we can compute the apparent axis ratio of $b/a$ (Binney 1985) at a random viewing angle ($\theta, \phi$) using Equations (12)–(15) in Ryden (2004). Repeating this calculation 5000 times, we obtain a model distribution of apparent axial ratio $b/a$, which is used to compare with the observed distribution of our sample.

We constrained the parameter set of $\mu$, $\sigma$, $\mu_C$, and $\sigma_C$ by fitting with the observed distribution of $b/a$. Ranges and steps of the parameters examined are listed in Table 1. The intrinsic $B/A$ ratio corresponding to the $\mu$ parameter is also shown in the parenthesis. The best-fitting set of parameters was obtained by $\chi^2$ minimization. We used a bin size of $\Delta(b/a) = 0.04$ for both the observed and model distributions of $b/a$. Once we had the best-fitting results, we repeated the fitting analysis with a finer grid centered on the best-fitting values. This refinement was done twice.

For the $b/a$ distribution of 318 single-component sBzK galaxies with $0.5 \leq n < 2.5$, the final best-fitting parameters are $\mu = -0.95^{+0.20}_{-0.15}$, $\sigma = 0.50^{+0.45}_{-0.15}$, $\mu_C = 0.28^{+0.03}_{-0.02}$, and $\sigma_C = 0.060^{+0.020}_{-0.015}$ with $\chi^2 = 0.98$. The errors are at 68% confidence level based on Monte Carlo realization; we derived the best-fitting parameters and repeated it 500 times by varying the observed distribution of $b/a$ within their Poisson noises. The model distribution of the best-fitting parameters is also shown with the observed one in Figure 9. The best-fitting $\mu = -0.95$ corresponds to the mean and the peak intrinsic $B/A$ ratio of 0.61 and 0.70, respectively. It is indicated that the intrinsic shape of the single-component sBzK galaxies is more likely to be bar-like or oval, rather than round.

Figure 12(a) shows the observed distributions of the axial ratios together with the best-fitting model and with $1\sigma$ deviated models ($\mu = -0.95^{+0.20}_{-0.15}$). The $1\sigma$ deviated models well bracket the observed distribution of apparent axial ratios. Figure 12(a) also shows that the parameter $\mu$ varies the $b/a$ distribution on the right side of the peak; the frequency of $b/a$ on that side increases with decreasing $\mu$ (i.e., increasing $B/A$). Changing $\sigma$ affects the shape of the $b/a$ distribution on both sides of the peak, but the effect is not so large (Figure 12(b)). The $\mu_C$ parameter affects the peak value of the $b/a$ distribution as seen in Figure 12(c). The peak of the apparent axial ratios increases with increasing disk thickness. The $\sigma_C$ parameter slightly affects the $b/a$ distribution around the peak (Figure 12(d)).

We divide the sample of the single-component sBzK galaxies into groups according to their properties and show their $b/a$ distributions in Figure 13. As mentioned above, dividing disk-like and spheroid-like objects at $n = 2.5$ is efficient down to $z_{850} < 24.5$ mag. Because the magnitudes of our sample are distributed to $z_{850} \sim 26$ mag, we make a subsample of sBzK galaxies with $z_{850} < 24.5$ mag. Figure 13(a) shows no significant difference of the $b/a$ histogram between the sBzK galaxies with $z_{850} < 24.5$ and $z_{850} < 26.0$ (the whole sample). Their best-fitting parameters are also consistent with each other as summarized in Table 1. Figure 13(b) shows the distributions for subsamples divided by their Sérsic index ($0.5 \leq n < 1.5$ and $1.5 \leq n < 2.5$). The distributions of the subsamples and the whole sample are very similar. Their best-fitting parameters agree with those of the whole sample almost within $1\sigma$ (Table 1). Figure 13(c) shows the distributions of the apparent...
Figure 11. Comparisons between input and recovered axial ratios ($b/a$) of artificial disk objects (left panel) and disk+bulge objects (right panel) in the $z_{850}$ image. (A color version of this figure is available in the online journal.)

For stellar-mass subsamples ($10^{9.5} M_\odot \leq M_{\text{stellar}} < 10^{10} M_\odot$ and $10^{10} M_\odot \leq M_{\text{stellar}}$), the distribution of subsamples with $10^{9.5} M_\odot \leq M_{\text{stellar}} < 10^{10} M_\odot$ is similar to that of the whole sample, while there seems to be a slight difference between the whole sample and the objects with $M_{\text{stellar}} \geq 10^{10} M_\odot$. However, the best-fitting parameters listed in Table 2 are in agreement mostly within 1σ errors, though the errors are rather large for some parameters. Figure 13(d) illustrates the distributions of the sBzK galaxies divided by their $B-K$ color ($B-K < 2.0$ and $2.0 \leq B-K$). Both $B-K$ subsamples show similar distributions to the whole sample. Table 2 also indicates that their intrinsic shape parameters agree with those of the whole sample. Finally, we divide the sample according to the photometric redshift ($1.3 \leq z_{\text{phot}} < 1.8$ and $1.8 \leq z_{\text{phot}} < 2.5$) in
Our analysis of the axial ratio distribution shows that the single-component sBzK galaxies have a bar-like or oval structure. At this redshift, the outermost isophote of \( \mu \) \( z_{850} \) \( \sim \) 28.0 mag arcsec\(^{-2} \) which we reach in this study corresponds to \( \mu_B \) \( \sim \) 23.5 mag arcsec\(^{-2} \) at \( z \sim 0 \) by considering the cosmological dimming and the average \( z_{850} - J \) color of the sample objects. This roughly corresponds to the surface brightness just beyond the bar end of present-day galaxies (e.g., Ohta et al. 1990). Are these direct progenitors of present-day barred galaxies? This is unlikely, because the fraction of barred galaxies decreases with increasing redshifts up to \( z \sim 1 \) (van den Bergh et al. 1996; Abraham et al. 1999; Sheth et al. 2008). Although there has been a debate on the evolution of the bar fraction among disk galaxies, a recent study with a large sample taken with HST/ACS shows that the bar fraction drops to \( \sim 10\%-20\% \) at \( z \sim 0.84 \) (Sheth et al. 2008). Sheth et al. (2008) pointed out in massive galaxies \( \geq 10^{11} M_\odot \) at \( z \sim 0.8 \) that the fraction is as large as in local massive galaxies, but in our sample such massive galaxies are rare and most of the sample galaxies have
stellar mass less than $10^{11} \, M_\odot$ (Figure 3). It is also worth noting here that the axial ratio distribution of nearby barred galaxies is rather flat (Ohta et al. 1990).

The radial surface brightness distributions of the single-component sBzK galaxies and their intrinsic axial ratios are similar to those of N-body bars due to the bar instability. The axial ratio $B/A$ of the $N$-body bars is $\sim 0.4-0.6$ and ratio $C/A$ is $\sim 0.3-0.5$ (e.g., Combes & Sanders 1981; Ohta et al. 1990; Athanassoula & Misiriotis 2002). Athanassoula & Misiriotis (2002) examined the morphological differences of bar structures formed in various disk models. The shape of the bar structure in their massive disk model (MD model), where disk dominates in the inner part of a galaxy, shows a good similarity with the statistical intrinsic shape of the sBzK galaxies. Azimuthally averaged radial profiles of the models also show exponential type. Meanwhile, a halo-mass-dominated model and an MD model with a central bulge show a much narrower bar structure with a rather flat-type radial surface brightness distribution, dissimilar to the observed properties obtained in this study. These suggest that the bar-like structure seen in the sBzK galaxies may form by bar instability which takes place when the disk mass fraction against dark halo mass within a disk radius exceeds the threshold (Ostriker & Peebles 1973). If this is the case, a key to the origin of the bar-like structure may be central condensation of baryonic matter as compared with dark matter distribution; a massive baryonic disk in a less massive dark matter halo within a certain radius can lead to bar instability resulting in such bar-like structure. Although the $Q$-parameter also plays a role in the bar instability, the shape of the galaxies may be a clue to understanding the dynamical formation process of disk galaxies.

Another possible cause for the origin of the bar-like structure may be galaxy interaction and/or merger (e.g., Noguchi 1987). Since many of the sBzK galaxies show multiple structure (46%), this could be a cause. But it should be noted that the analyzed sample of the sBzK galaxies are the single-component sBzK galaxies and thus give no clear sign for strong close galaxy interaction. Cold gas accretion onto a galaxy halo (e.g., Dekel et al. 2009) may also form a non-axisymmetric structure. However, this kind of cold gas accretion seems to more preferentially occur at an intersection of filamentary structures of the universe, and its effect would dominate in a massive galaxy. Dekel & Birnboim (2006) showed that the cold gas accretion affects in halo masses larger than $\sim 10^{12} \, M_\odot$, thus $\sim 10^{11} \, M_\odot$ in baryonic mass, while the stellar mass of our sample is mostly less than $\sim 10^{11} \, M_\odot$. Hence this mechanism would not be expected to dominate in the sBzK galaxies.

The axial ratio distributions peaking at $b/a \simeq 0.4-0.5$ are seen among LBGs at $z \sim 3$ and 4 (Ravindranath et al. 2006) and Lyman $\alpha$ emitters at $z = 3.1$ (Gronwall et al. 2010). Although these higher redshift star-forming galaxies, in particular LBGs, may not be progenitors of present-day disk galaxies as mentioned in Section 1 and we see their morphology in UV wavelength, these galaxies presumably have similar bar-like structure as the sBzK galaxies, and their origin might be the same as that for the sBzK galaxies.

Figure 13. Distributions of the apparent axial ratios of sBzK subsamples. The whole sample of the single-component sBzK galaxies with $0.5 \leq n < 2.5$ is indicated by a solid line in all figures. Panel (a) shows the subsample of sBzK galaxies with $z_{900} < 24.5$ mag. We divide the galaxies with $0.5 \leq n < 2.5$ into subsamples according to their Sersic index and their stellar mass in panels (b) and (c), respectively. Panel (d) shows the $b/a$ distribution of the subsamples divided by their $B-K$ color. The subsamples are divided so that they have approximately the same number of galaxies. Panel (e) shows distributions of subsamples divided by their photometric redshifts. Ranges of redshifts are selected so that both subsamples are in the comparable comoving volume. The histograms are normalized so that the area is unity. (A color version of this figure is available in the online journal.)
What are the descendants of the sBzK galaxies? The properties described in Section 4 and similarity in size and the stellar-mass density point to the sBzK galaxies being progenitors of present-day disk galaxies. However, since they do not show the round disk structure, a transformation from the bar structure to the round disk structure should occur if the sBzK galaxies have really evolved into disk galaxies. The axial ratio distribution of star-forming galaxies at $z \sim 1.2$ is rather flat (Ravindranath et al. 2006), suggesting that galaxies at $z \sim 1.2$ have the round disk structure. If the sBzK galaxies are growing into these galaxies at $z \sim 1.2$, the elapsed time is about 1–2 Gyr from $z \sim 1.5$ to $z \sim 1.2$. Thus a rapid transformation mechanism is required. One possibility is that they are gas rich and will make a gas-rich merger resulting in an exponential round disk (e.g., Springel & Hernquist 2005). Alternatively, a bulge or a central mass condensation at the center of a galaxy may dissolve the bar structure. A growing central mass condensation with a mass of a few to 10% of the disk can dissolve the bar structure with a timescale of a few Gyr and the bar structure is totally destroyed after $\sim$5 Gyr for the MD-type disk (Athanassoula et al. 2005). Thus the growth of a bulge and/or supermassive black hole at the center of the galaxies may also cause the shape transformation.

7. CONCLUSION

We study the intrinsic structure of sBzK galaxies at $z \sim 2$ in the GOODS-North field. 1029 sBzK galaxies were selected down to $K_{AB} < 24.0$ mag. Fifty-four percent of them show a single component in the ACS/F850LP image, which covers the rest-frame UV ($\sim$3000 Å) wavelength. Structural parameters of the single-component sBzK galaxies were obtained by fitting the two-dimensional light distributions in the ACS/F850LP image with a single Sérsic profile. We found that most of them show a Sérsic index of $n = 0.5$–2.5, indicative of a disk-like structure. The effective radii typically range from 1 kpc to 3 kpc. After correcting the effective radii to those in the rest-frame optical wavelength, we found in the stellar-mass–size diagram that most of the single-component sBzK galaxies are distributed in the same region as $z = 0$–1 disk galaxies studied by Barden et al. (2005). This indicates that most of the sBzK galaxies show a surface stellar-mass density comparable to the local and $z \sim 1$ disks.

The peak of the Sérsic-index distribution at $n \sim 1$ and the comparable surface stellar-mass density to the local disks suggest that most of the single-component sBzK galaxies are disk-like. We further examined their intrinsic shape by deriving the distribution of apparent axial ratio ($b/a$) of the sBzK galaxies to see whether they are really disk-like galaxies. The distribution is skewed toward low $b/a$ values with a peak of $b/a \sim 0.4$, in contrast to a flat distribution for round disks. We compared the axial ratio distribution to the model distributions assuming a triaxial ellipsoid model with axes $A > B > C$. The best-fitting parameters correspond to the mean face-on ratio ($B/A$) of $0.61^{+0.03}_{-0.08}$ and disk thickness ($C/A$) of $0.28^{+0.04}_{-0.01}$. This indicates that the single-component sBzK galaxies have a bar-like shape rather than a round disk shape.

This bar-like structure is unlikely to be a direct progenitor of present-day barred galaxies, since the fraction of barred galaxies decreases with increasing redshift. The obtained bar structure seems to be similar to that formed through bar instability; if this is the case, the intrinsic shape may give us a clue to understanding the dynamical evolution of baryonic matter in a dark matter halo. If the sBzK galaxies really evolve to the present-day disk galaxies, some mechanism forshape transformation is required. Gas-rich merger or a bulge and/or supermassive black hole growth at the center of the galaxies may be responsible for this shape transformation.

Finally, it is important to note that we studied the intrinsic shape of the single-component sBzK galaxies in the rest-frame UV wavelength, where structure tends to be influenced by star-forming activities. In order to know the distribution of the stellar component, further studies in the rest-frame optical wavelength with high-resolution images taken with HST/WFC3 are desirable.
