We propose a spin-mechanical device to control and detect spin currents by nanomechanical torque. Our hybrid nano-electro-mechanical device, which contains a nanowire with a ferromagnetic-nonmagnetic interface, is designed to measure or induce spin polarized currents. Since spin carries angular momentum, a spin flip or spin transfer process involves a change in angular momentum—and hence, a torque—which enables mechanical measurement of spin flips. Conversely, an applied torque can result in spin polarization and spin current.

INTRODUCTION

Electronics and information processing with spins promise to be anything but conventional \[1\], \[2\]. In spin-based electronics, information is injected, stored, transferred, or manipulated with the spin degree of freedom. The realization of its importance—and the ensuing excitement—stems from the fact that successful incorporation of spins into conventional semiconductor technology will allow to combine both information storage and information manipulation within a single platform. Recent discovery of a number of spin-based phenomena such as giant magnetoresistance \[8\] has also marked the beginning of a new era with spintronics \[1\], \[2\], and spin-based quantum information processing \[4\]. The transport properties of d-electrons in ferromagnetic transition metals like Fe, Co, Ni, and their contribution to the ferromagnetism are also of important fundamental interest \[3\] .

At the heart of spintronics is detection and control of electron spins moving through a ferromagnetic-metallic or ferromagnetic-semiconductor heterostructure. Towards this end, there have been a large number of important experiments \[10\] and theoretical works \[11\], leading to a whole new dictionary for spin-based electronics—spin diode, spin transistor, spin pump, spin battery and spin filter \[12\] . Here, we propose a spin-mechanical device for detection and control of spins in hybrid magnetic-nonmagnetic structures by mechanical torque.

Spin transport and nanomechanics form the underlying basis of the proposed spin-mechanical device, which is capable of detecting, controlling and creating both spin transport and spin population. The central concept of its function is rather simple: spin carries angular momentum and a change in the angular momentum due to spin transport creates a torque, which can be detected by a nanomechanical torsion oscillator.

The deceptive simplicity of the idea contrasts its rich history, both in theory and experiment. The original proposal to detect changes in the magnetization by measuring the associated torque dates almost a century back to the work of Richardson \[12\] and Einstein and de Haas \[13\] . The reverse effect, inducing magnetization by rotation has been suggested and measured soon by Barnett \[14\] . Another mechanism is the associated Wiedemann effect \[15\] : a current flowing through a ferromagnet, such as a Ni– or Fe wire, in a parallel magnetic field induces a torque on the wire due to magnetoelastic interactions.

Motivated by these historical experiments it was recently pointed out that a current flowing through a ferromagnetic-nonmagnetic (FM-NM) interface produces a mechanical torque. In a ferromagnet, a current has an associated spin current, which is absent in a nonmagnetic metal. Therefore, there is a sink or source of angular momentum at an FM-NM interface, depending on the current direction, which results in a torque \[16\] , which can be transferred into a mechanical torque of the device \[17\] . This is precisely the underlying principle of the classic optical experiment by Beth \[18\] in which the change in the angular momentum of circularly polarized photons through an optically active glass is measured; the torque on the glass plate results due to the change in polarization at the interface. This allowed for the first time to prove experimentally the quantization of the spin of photons.

A measurement of the torque at an FM-NM interface would allow for a determination of the relative contributions of different types of electrons to the current, e.g., of s and d electrons in the case of Fe \[3\] . Those electrons are polarized to a different degree because of their different bandwidths. From an experimental measurement of the tunneling density of states, magnetic polarizations of \(\alpha = .11, .34, .44\) for Ni, Co and Fe have been estimated, while a theoretical calculation for s-electrons alone would...
FIG. 1: (Color online) Schematic diagram, showing a suspended ferromagnetic-nonmagnetic (FM-NM) wire. The black arrow denotes the direction of the magnetisation. A spin-transfer process at or beyond the FM-NM interface torts the wire as indicated.

give for Ni, αs = .01 [2]. Until now, there is no direct measurement available of the relative contribution of the s and d electrons to the current.

**SPIN FLIP TORSION BALANCE**

It is the purpose of this article to show that this spin flip torsion balance effect can be strongly enhanced in a nanomechanical device when a nanowire containing a FM-NM interface is grown on top of a suspended nanoelectro-mechanical structure (NEMS). Thereby, the spin transport can be measured by the induced mechanical torque in the NEMS torsion device. The inverse is also true: a torque at the FM-NM interface produces a potential difference between the two metals [14, 19]. Accordingly, a spin current can be generated by applying an external torque. In this paper, we perform a detailed analysis to show that such a device can be used to detect, control and induce spin current.

In a nanowire with a ferromagnetic (FM) and a nonmagnetic (NM) part, the ferromagnet is uniformly spin polarized in a direction parallel to the wire. Application of a magnetic field parallel to the wire further elongates the magnetization. When a current $I$ is passed through the wire, a fraction $\alpha/2$ of the electrons passing through the interface between the FM and NM flip their spin. Here, $\alpha$ is the degree of magnetic polarization of the electrons contributing to the current in the ferromagnet.

Each spin flip results in a change in the angular momentum $\Delta L = \hbar$. The number of electrons $\Delta N$ passing through the interface in a time interval $\Delta t$ is $\Delta N = I \Delta t/e$, where $I$ is the electrical (charge) current, and $e$ the electron charge. The associated change in angular momentum is

$$\Delta L/\Delta t = (\hbar \alpha/2)I/e,$$

which results in a torque

$$T^\text{spin} = \frac{\hbar}{2} \alpha \frac{I}{e} \hat{x} .$$

Here, $\hat{x}$ is the unit vector along the wire axis. The higher the spin polarization of the conducting electrons, the larger is the resulting torque. Thus, that torque is a direct measure of the spin-polarisation of the itinerant electrons in the ferromagnet. If the current increases, the resulting torque increases linearly.

There is an additional contribution $T^\text{W}$ to the net torque because of the Wiedemann effect. This contribution is orders of magnitude smaller than $T^\text{spin}$ in nanomechanical systems as we show below. $T^\text{W}$ originates from the axial magnetic field $H_c = I/2\pi R$ perpendicular to the magnetization axis of the FM part of the nanowire in presence of a current $I$. It leads to small changes in the direction and the absolute value of the magnetization by the magneto-elastic interaction. The resulting torque $T^\text{W}$ has an associated torsion angle $\theta_W = (\lambda \ell/R) \delta M_e/M_0$. Here, the radius of the wire is $R$, its length $\ell$, and $M_0$ is the magnetization along the wire axis. $\lambda = \Delta \ell/\ell$ is the magnetostrictive coefficient which characterizes the relative length changes $\Delta \ell/\ell$ due to the changes of the magnetization $\delta M$. Here, $\delta M_e = \chi_p H_c$ is the field generated by the current $I$ and $\chi_p$ is the magnetic susceptibility to the magnetic field $H_c$, pointing circularly around the wire axis, when the single domain ferromagnet is polarized along the wire. The torque is then given by $T^\text{W} = K\theta_W$, where for a wire, $K = \frac{\pi}{2} GR^4/L$ and $G$ is the shear modulus of the oscillator. The ratio between $T^\text{W}$ and $T^\text{spin}$ is

$$\frac{T^\text{W}}{T^\text{spin}} = \frac{R^2 Ge\lambda \chi}{2\alpha M_0} .$$

The magnetostriction coefficient $\lambda$ is in general quite small (relative to the unpolarised state, it is on the order of $10^{-6}$) and both its sign and magnitude depend on the material and the material growth direction. Here, we are interested in the magnetostriction as caused by the reorientation of the magnetisation due to the circular field, relative to the state when the wire is fully polarized along the wire. In that case, $\lambda$ is a function of the magnetization $M_0$ and applied magnetic field $H_c$, and it displays strong hysteresis [20]. From magnetoelastic theory one expects $\lambda \approx \Lambda (\delta M/M_0)^2$ [20], although the exact functional form may depend on the material and crystal orientation.

From magnetostriction measurements on Fe or Ni [20] we estimate $\Lambda \approx 10^{-5}$, when the ferromagnet is magnetized along the wire with typical magnetization $M_0 = 4\pi 10^6 A/m$. We find with $G = 10^{10} N/m^2$,

$$\frac{T^\text{spin}}{T^\text{W}} = \frac{\alpha 8.5 \times 10^{-5}}{\rho^4 \lambda^3 \beta^2} ,$$

where $\rho$ is the resistivity of the material. The resulting torque is then

$$T^\text{spin} = \frac{\alpha 8.5 \times 10^{-5}}{\rho^4 \lambda^3 \beta^2} I \hat{x}.$$
where $R = \rho(mm)$, and $j = j(A/mm^2)$ is the current density. In the classical macroscopic experiments with $\rho \approx 0.1$ and $j = 1$, the Wiedemann effect and the spin flip torsion effect can be of the same order of magnitude. However, in a nanomechanical torsion oscillator, the wire can be as thin as $\rho = 10^{-4}$, while the current density can still be $j = 1$, the spin flip torsion balance can exceed the Wiedemann effect by orders of magnitude. When applying the circular magnetic field, the single magnetic domain, magnetised along the wire has some rigidity so that the corresponding magnetic susceptibility $\chi_c$ is small. Taking for a ferromagnetic cylinder polarised along its axis a typical value $\chi_c = 1$, one finds $T_{spin}/T_W \approx 10^{12}$. Although the circular magnetic susceptibility can depend on the growth direction of the ferromagnetic film, and can change with its dimension, we can conclude that the Wiedemann effect is negligible for any theoretically possible value of the circular magnetic susceptibility, ranging between the Pauli susceptibility $\chi_P \sim 10^{-4}$, and values for macroscopic ferromagnets $\chi \sim 10^3$.

**Spin-Mechanical Balance:** The spin-transfer torque can be measured with a suspended NEMS torsion balance to which the half-ferromagnetic, half-nonmagnetic nanowire is rigidly attached, as shown in Fig. 1. The magnitude of the torque, Eq. (4) along the wire axis is given by

$$T_{spin} = 3.3 \times 10^{-19} \alpha I Nm,$$

where $I$ is the current in units of mA. Thus, the torque is within the sensitivity range of existing NEMS oscillators. The torque caused by the finite spin flip rate, Eq. (3), is in balance with the torque due to the elastic torsion of the wire, as well as a torque due to the finite inertia of the wire, and a friction torque when the torsion angle changes in time.

For low but constant driving currents the electron transfer rate at the interface can be smaller than the spin-flip scattering rate $1/\tau_s$. In this case, the spin transfer rate $1/\tau$ explicitly.

Let us consider the situation when the current is reduced such that the transfer rate $I/q$ becomes smaller than $1/\tau_s$, and the spin flips occur one by one.

**RANDOM SPIN FLIP**

For low but constant driving currents the electron transfer rate at the interface can be smaller than the spin-flip scattering rate $1/\tau_s$. In this case, the spin transfer
torque can be considered to occur randomly at times, $t_i$, with the average amplitude,

$$T_R = \hbar \alpha \frac{1}{2 \tau_s} = \frac{\alpha}{2} 1.1 \times 10^{-25} \text{Nm} \frac{1}{\tau_s}, \quad (11)$$

where $\tau_s = \tau_s(ns)$. Thus, the time dependent driving torque can be modeled by

$$T_{\text{spin}}(t) = T_R \sum_i \left[ \Theta(t - t_i) - \Theta(t - \tau_s - t_i) \right], \quad (12)$$

where $\Theta(x)$ is the step function, $\Theta(x) = 1$ for $x > 1$, and $\Theta(x) = 0$, otherwise. The equation of motion Eq. (5) with the right hand side, $T_s(t)$, can be solved by Fourier transform:

$$\theta(t) = \int \frac{d\omega}{2\pi} \frac{1}{\delta + i\omega K - \omega^2 J + i\gamma \omega} \sum_i \exp\left(-i(\omega(t - t_i)) - \exp(i\omega(t - \tau_s - t_i))\right) \quad (13)$$

where $\delta \to 0^+$. Performing the residuum integral, we obtain, for $\omega_0 < 1/\tau_s$, the time dependence of the torsion angle reduces to a sum of sinusoidal oscillators with phase shifts at random times $t_i$, when a single spin flip occurs.

$$\theta(t) = \frac{\hbar \alpha}{2 J \omega_0 \sqrt{1 - 1/\Omega^2}} \sum_{i, t_i < t} \exp\left(-i(\omega(t - t_i)) - \exp\left(i\omega(t - \tau_s - t_i)\right)\right) \sin\left((t - t_i)\omega_0 \sqrt{1 - 1/\Omega^2}\right). \quad (14)$$

While the amplitude of the torque does depend on the spin flip rate $1/\tau_s$, the torsion angle does not depend on it, and is strictly a function of the current $I$. For $I/e \gg \omega_0$ it can be shown that Eq. (14) reduces to Eq. (9).

When the resonance frequency of the oscillator exceeds the spin flip rate, $\omega_0 > 1/\tau_s$, one obtains for large quality factor $Q \gg 1$, the simplified expression,

$$\theta(t) = \theta_0 + \theta_R \sum_{t_i < t} \cos\left((t - t_i)\omega_0\right) - \theta_R \sum_{t_i + \tau_s < t} \cos\left((t - t_i - \tau_s)\omega_0\right). \quad (15)$$

Here $\theta_R = T_R/K$. Thus, when $\omega_0 > 1/\tau_s$, both the torque and the amplitude of the time dependent torsion angle $\theta_R$ do depend directly on the spin flip rate $1/\tau_s$.

The nature of the random spin-flip torque is not known a priori. It depends on the microscopic physical mechanism of spin relaxation via a number of channels such as coupling to local magnetic moments, nuclear magnetic moments, and dominantly, via spin–orbit interaction to phonons by the Elliot-Yafet mechanism\[24, 25\]. The spin-orbit interaction modified by phonons can break momentum conservation in a periodic crystal\[24, 28\] and hence result in relaxation. Furthermore, as shown by D’yankov and Perel\[29\], in crystals lacking momentum-inversion symmetry, the lifting of spin degeneracy by spin-orbit scattering\[30\], operates as a momentum-dependent internal magnetic field, and contributes to spin relaxation. Temperature dependence of the spin relaxation rate $1/T_1$ in the Elliot-Yafet mechanism is the same as the temperature dependence of resistivity: (i) $1/T_1 \sim T$ for $T > T_{\text{Debye}}$, (ii) $1/T_1 \sim T^5$ (at low temperature). D’yankov-Perel mechanism results in a spin relaxation rate proportional to the momentum relaxation time.

In the nonlinear regime, the resonance of the oscillator in the presence of random torques can be enhanced by nonlinear self-excited oscillations. This effect is due to the nonlinear dependence of the torque on the angle $\theta$\[31\]. In fact, Eq. (5) becomes nonlinear with the magnetization dynamics.

**SPIN CURRENT GENERATION**

Applying a torque, a potential difference along the wire axis is created\[10\], as given by $e V(t) = -(2 m/\hbar) Vol. M_z d\theta/dt$. With proper design of the device this potential can be used to drive a time dependent current with density

$$j_B(t) = -\sigma \pi R^2 \frac{2m}{e^2 g} M_z \frac{d\theta}{dt}. \quad (16)$$

where $\sigma$ is the conductivity, and $g$ is the gyromagnetic coefficient. Writing $M_z = M_z(10^6/4\pi)A/m$, where the dimensionless $M_z$ is typically on the order of one, and $R = \mu m$, we obtain inserting as the typical metallic conductivity $\sigma = 10^7/\Omega m$, $j_B \sim -10^4 \mu M_z (d\theta/dt) s A/cm^2$.

Another source of potential difference is from magnetostriction: when the magnetized wire is twisted, it results in a circular component. This so-called Matteucci effect induces a potential difference, and, hence, in a closed circuit a current density\[32\]:

$$j_M = -2\sigma \frac{R^2}{L} \lambda G \frac{\chi}{M_z} \frac{d\theta}{dt}. \quad (17)$$

Inserting the typical values of $G, \lambda, \sigma, L$, and $\chi$, as given above, we obtain $j_M \sim -10^{-3} \rho^2/L(d\theta/dt) s A/cm^2$, where $L = \mu m$, which is thus negligible compared to the current due to the Barnett effect, Eq. (15).

**EXPERIMENTAL REALISATION**

Sensitive measurement of nanomechanical torque generated due to spin transfer in the FM-NM nanowire can be done in a number of configurations. We discuss a specific device which allows ultra-high detection sensitivity. Figure 2 shows the schematic diagram of such a hybrid...
The hybrid structure contains three sets of electrical components. The first one (5-6-7-8) is the central FM-NM nanowire with a typical thickness of 40 nm – 100 nm and lithographically-defined width of 60 nm – 100 nm. The other two electrical components (1-2 and 3-4), the two electrodes symmetrically placed on both sides of the large outer paddles, are designed to allow both detection and control of the torque \( \omega / 2 \pi Q \), and the resonance frequencies of the device entering Eq. (5). The nanowire on top of a suspended two-element torsion oscillator, the torque generated in the nanowire on top of a suspended two-element torsion oscillator modifies accordingly the mechanical torque, which twists the suspended structure since the FM-NM wire is rigidly attached to the torsion oscillator. Because of small size, this device has extremely high torque sensitivity at low temperatures. Conversely, a spin polarization can be induced by applying a torque to the outer paddle, which will result in an imbalance in the spin states. The probability of the spin population along the nanowire is governed by the conservation of angular momentum, which enables the device to operate as a spin battery.

In summary, we propose a novel nanomechanical device, which contains a ferromagnetic–nonmagnetic nanowire on top of a suspended two-element torsion oscillator. Since the nanowire is fabricated on top of the torsion oscillator, the torque generated in the nanowire will translate to a torque in the entire structure, including the torsion oscillator, modifying accordingly the mechanical parameters, the inertia \( J \), the bulk modulus \( G \) and the resonance frequencies of the device entering Eq. (5).

The hybrid structure contains three sets of electrical components. The first one (5-6-7-8) is the central FM-NM nanowire with a typical thickness of 40 nm – 100 nm and lithographically-defined width of 60 nm – 100 nm. The other two electrical components (1-2 and 3-4), the two electrodes symmetrically placed on both sides of the large outer paddles, are designed to allow both detection and control of the torque \( \omega / 2 \pi Q \), and hence of the spin transfer. In presence of a magnetic field, applied in such a way that the torsion of the outer paddles will enclose a finite area, the torsion of the structure will induce an electromotive voltage on the electrode (1-2) by the Faraday effect. Likewise, an applied current through the other electrode (3-4) can generate a control force \( F_{\text{drive}} = I_{\text{control}} LB \) or torque on the structure. This control torque can be used, for example, to induce spin polarization in the structure.

Measurement of the spin-induced torque and application of the control torque in the proposed device can be performed by the magnetomotive technique \( \text{[23]} \). Elsewhere, we have discussed in detail low temperature measurements with torsion oscillators similar to the one schematically shown in Figure 2 \( \text{[23]} \). Because of low temperature and small size, the proposed device can operate with unprecedented force sensitivity of \( 10^{-16} \text{N}/\sqrt{Hz} \) or a corresponding torque sensitivity of \( 10^{-21} \text{N.m}/\sqrt{Hz} \), as recent experiments on similar devices have demonstrated \( \text{[23]} \). Correspondingly, the minimum detectable force or torque can be obtained by using the intrinsic bandwidth of the device \( \omega / 2 \pi Q \). For a similar control device, we have already obtained a minimum detectable force of \( 48 \times 10^{-18} \text{N} \) or a minimum detectable torque of \( 48 \times 10^{-23} \text{N.m} \) for a moment arm of \( \sim 10 \mu m \) at a temperature of 4 K \( \text{[33]} \). Elsewhere \( \text{[23]} \), we have extensively characterized a set of control torsion devices and their dependence on temperature, field, size, and frequency.

Experimental realization of the proposed device relies on the nanofabrication of a multilayer nanomechanical structure. Recently, we have successfully fabricated a set of suspended devices of single-crystal silicon with a half gold, half cobalt nanowire designed to resonate in the range of 1-10 MHz. For device parameters of \( L = 10 \mu m \), \( R = 100 nm \), \( \omega_0 / 2 \pi \approx 1 \text{MHz} \), and \( Q \approx 10^4 \) (at 300 mK), the maximum torsion angle due to the spin torque is \( \approx 4.0 \times 10^{-2} \) radian for a drive current of 10 nA. For comparison, the rms value of the fluctuations in the torsion angle due to thermal noise, Eq. (10), in the same device is \( \sim 2 \times 10^{-5} \) radian at 300 mK. To observe the maximal torsion, the magnetisation of the Cobalt nanowire is required to be oriented parallel to the wire axis. Indeed, it has been shown experimentally, with the magneto optical Kerr effect, that the easy axis of Cobalt thin films is inplane for a film thickness exceeding \( d = 1 \mu m \). Below that a reorientation perpendicular to the film has been observed \( \text{[34]} \), and explained due to the crystal and interface anisotropy, which overcomes the shape anisotropy when the film contains only few monolayers \( \text{[35]} \). Ideally, one should have a single domain along the wire, which is in the chosen wire geometry the one favoured by the shape anisotropy. If one has domains with alternating magnetisation along the wire, there will be excitation of torsional modes with wave lengths on the order of the domain size, in addition to the zero mode, considered above. In order to maximize the torsion signal, one can obtain a single domain by applying a weak magnetic field of not more than 100 Gauss along the wire \( \text{[34]} \).

**CONCLUSIONS**

In summary, we propose a novel nanomechanical device, a sensor of spin dynamics at the ferromagnetic–nonmagnetic interface of a wire fabricated on top of a suspended torsion oscillator. We explicitly derive closed-form expressions for the torque created by spin currents,
and other physical mechanisms. This elementary device can be used to detect, control and induce spin currents by selectively applying and measuring the torque in the nanomechanical resonator. The basic structure can be further modified to create devices for eventual use in spintronics, and spin information processing.
