Abstract

Amphiphilic block copolymer solutions form various micellar structures including micelles and vesicles. We applied the density functional theory for block copolymers which we have proposed to amphiphilic block copolymer systems. The 3 dimensional simulation for AB diblock copolymer solutions and AB diblock copolymer / A homopolymer blends has been done and it is shown that the spherical micelles, cylindrical micelles and spherical vesicles are formed. It is also shown that the phase diagram for AB diblock copolymer / A homopolymer blends qualitatively agrees with the phase diagram obtained by the experiment.

1 Introduction

Block copolymers dissolved in solvent or other polymers assemble spontaneously to form various self-organized structures such as spheres, rods and vesicles [1]. What structure is formed is a question very important in colloid science, but difficult to answer since the structure depends on many parameters such as the block ratio, the affinity between component units, the polymerization index and the volume fraction of the block copolymers. Attempt has been made to predict the micellar structure by computer simulation. Since the process of self-organization involves many molecules and is very slow, atomistic molecular dynamics simulation cannot be used for this purpose.

Various coarse grained models have been used to study the formation of the micellar structure. Larson et al. [2, 3] used a lattice model to show that amphiphilic molecules actually form micellar structure. Bernardes [5] studied the vesicle formation by the Larson type lattice model. Yamamoto [7] demonstrated that the DPD (dissipative particle dynamics) [6] can show the formation and various structural change of vesicles. Similar attempt has been done by Noguchi [8, 9] et al. for small molecule surfactant solutions. They studied formation and deformation of surfactant vesicles by Brownian Dynamics (BD).

In these models it is not straightforward to connect the coarse grained model with the underlying atomistic model. (Some parameters can be associated with the mean field parameter. For example, the interaction parameters used in DPD can be mapped onto the Flory-Huggins \(\chi\) parameter [6, 10]. But this is not always successful, and needs more validation.)

Other approach which takes into account of the molecular characteristics is the dynamic mean field theory which is based on the self consistent field (SCF) theory [11, 12, 13, 14]. In this approach, it is possible to determine the model parameters from the atomistic models for certain classes of polymers.
For periodic systems, computationally efficient and fast SCF method has been developed [15] which uses eigen functions. The method has been applied for AB diblock copolymer / A homopolymer blends which forms micelles [16]. However the method is not best suited to study the micelles or vesicles which does not form periodic structures.

For non-periodic systems, the real-space SCF simulation method has been frequently used. The method is based on the real-space calculation of the path integral and needs large CPU power and memory. Although considerable development has been achieved due to the improvement of algorithms [11, 12] and in models [13], it is still computationally demanding for large systems.

Some works has been done for micellar systems using the real-space SCF simulation. For example, Fraaije et al. [17] and Lam et al. [18] have studied rather dense block copolymer solution with the mean field parameters calculated from the experimental data and shown that they form the micellar structure. Fraiije and Sevink [19] also demonstrated various intriguing self organized structure formed in the droplet of concentrated solution of block copolymers in equilibrium with the outer solvent phase.

While these applications of SCF have achieved successful results, the dilute micellar systems have not been studied yet except for a few works. He et al. [20] performed 2 dimensional SCF calculation for the dilute AB diblock copolymer solution (AB diblock copolymer / S solvent mixtures) and showed that the AB diblock copolymer actually forms 2 dimensional vesicles. Though this is an important achievement, the 2 dimensional simulation poses problems in the interpretation of the results. The spherical vesicles are 3 dimensional objects and cannot be handled by 2 dimensional simulation. At present, the 3 dimensional real-space SCF simulation for micellar systems costs too much CPU power and memory and difficult to perform.

The computational cost of the dynamic mean field theory can be reduced drastically if one knows the free energy of the system as the functional of the density distribution of each component. The crucial point of this approach is the expression of the density functional. Earlier works [21, 22] used heuristic arguments for the expression, and was difficult to generalize. In the previous paper [23], we have proposed a general expression for the density functional which involves the same parameters appearing in the SCF theory. We have shown some preliminary results which shows the formation of the self organized structure for the mixture of block copolymers and homopolymers.

In this paper, we shall show that our free energy functional can be applied and is effective for the study of 3 dimensional micellar systems. We shall show that micelles and vesicles are formed from the homogeneous state. (As far as we know, this is the first 3 dimensional simulation of the vesicle formation from the homogeneous state using the continuous field model.) We shall discuss the relationship between the micellar structure and the molecular parameters (volume fractions, $\chi$ parameters, the block ratio). We shall also discuss the comparison between the present simulation and experiments and the SCF simulation by He et al. [20].

2 Free Energy Functional Model

In this paper, we discuss two systems: one is the AB diblock copolymer solution (the solvent being a small molecule of C), and the other is a polymer blend, a mixture of AB diblock copolymer and A homopolymer. In both systems the block copolymers act as the surfactant and form the self organizing, micellar structures.

In the density functional theory, the free energy $F$ of the system is written as a functional of the density distribution of the monomers belonging to various subchains in the system. The subchains are indexed by $(p, i)$, where $p$ and $i$ refer to the polymer, and the subchain in the polymer. In the present problem, the system consists of three subchains (AB,A), (AB,B) and (S,S), each of which stands for the A block of the AB diblock copolymer, the B block of the AB diblock copolymer, and the matrix, which is the C solvent in the case of solution, and A homopolymer in the case of polymer blend.

Let $\phi_{pi}(r)$ be the volume fraction of the monomers belonging to the $(p, i)$ subchain at point $r$. 

We use the following free energy functional model \[23\].

\[
F \left( \{ \phi_{pi}(r) \} \right) = \sum_{p,ij} \int dr dr' \left[ 2 \sqrt{f_{pi} f_{pj}} A_{p,ij} G(r - r') \sqrt{\phi_{pi}(r) \phi_{pj}(r')} \right] \\
+ \sum_{p_i} \int dr f_{pi} C_{pi,ii} \phi_{pi}(r) \ln \phi_{pi}(r) \\
+ \sum_{p_i \neq j} \int dr 2 \sqrt{f_{pi} f_{pj}} C_{p,ij} \sqrt{\phi_{pi}(r) \phi_{pj}(r)} \\
+ \sum_{p_i} \int dr \frac{b^2}{24 \phi_{pi}(r)} |\nabla \phi_{pi}(r)|^2 \\
+ \sum_{p_i,j} \int dr \frac{\chi_{pi,qj}}{2} \phi_{pi}(r) \phi_{qj}(r)
\]

(1)

where \(G(r - r')\) is the Green function which satisfies \(-\nabla^2 G(r - r') = \delta(r - r')\), \(f_{pi}\) is the block ratio of the \(i\)-th subchain of \(p\)-th polymer, \(b\) is the effective bond length and \(\chi_{pi,qj}\) is the Flory-Huggins \(\chi\) parameter. \(A_{p,ij}\) and \(C_{p,ij}\) are determined from \(b\), \(f_{pi}\), the degree of polymerization \(N_p\) and the structure of block copolymer (see Ref. \[23\] for detail).

The free energy functional eq (1) reduces to the following form for the AB diblock copolymer / S solvent blends.

\[
F \left[ \phi_A(r), \phi_B(r), \phi_S(r) \right] = \sum_{i,j} \int dr dr' 2 \sqrt{f_i f_j} A_{ij} G(r - r') \sqrt{\phi_i(r) \phi_j(r')} \\
+ \int dr \left[ f_A C_{AA} \phi_A(r) \ln \phi_A(r) + f_B C_{BB} \phi_B(r) \ln \phi_B(r) \right] \\
+ \int dr 4 \sqrt{f_A f_B} C_{AB} \sqrt{\phi_A(r) \phi_B(r)} \\
+ \int dr \left[ \frac{b^2}{24 \phi_A(r)} |\nabla \phi_A(r)|^2 + \frac{b^2}{24 \phi_B(r)} |\nabla \phi_B(r)|^2 \right] \\
+ \int dr \frac{1}{N_S} \phi_S(r) \ln \phi_S(r) \\
+ \int dr \frac{b^2}{24 \phi_S(r)} |\nabla \phi_S(r)|^2 \\
+ \sum_{i,j} \int dr \frac{\chi_{ij}}{2} \phi_i(r) \phi_j(r)
\]

(2)

Here we dropped the index \(p\), which specify the polymer species, for simplicity. Thus \(\phi_A(r)\), \(\phi_B(r)\) and \(\phi_S(r)\) stands for the density of the A component of the block copolymer, the density of the B component of the block copolymer and the density of the matrix (C solvent in the case of polymer solution and A homopolymer in the case of polymer blend). \(A_{ij}\) and \(C_{ij}\) for diblock copolymer \((i, j = A, B)\) is given in Appendix A.

It is convenient to introduce the new order parameter (the \(\psi\)-field) defined via the following equation \[23\];

\[
\psi_i(r) \equiv \sqrt{\phi_i(r)}
\]

(3)
With this order parameter, eq (2) is rewritten as

\[
F [\psi_A(r), \psi_B(r), \psi_S(r)] = \sum_{i,j} \int \int d^2r d^2r' 2\sqrt{f_i f_j} A_{ij} G(r-r') \psi_i(r) \psi_j(r') \\
+ \int dr \left[ 2f_A C_{A} \psi_A^2(r) \ln \psi_A(r) + 2f_B C_{B} \psi_B^2(r) \ln \psi_B(r) \right] \\
+ \int dr 4\sqrt{f_A f_B} \psi_A(r) \psi_B(r) \\
+ \int dr \left[ \frac{b^2}{6} |\nabla \psi_A(r)|^2 + \frac{b^2}{6} |\nabla \psi_B(r)|^2 \right] \\
+ \int dr \frac{2}{N_S} \psi_S^2(r) \ln \psi_S(r) \\
+ \int dr \frac{b^2}{6} |\nabla \psi_S(r)|^2 \\
+ \sum_{i,j} \int dr \frac{\psi_i^2(r) \psi_j^2(r)}{2} \\
\]  

3 Simulation

We performed the simulation to get the equilibrium structure of the diblock copolymer solution. To get the equilibrium structure numerically, we minimized the free energy functional eq (4) by using the algorithm shown in this section.

3.1 Constraints

The minimization of the free energy was done under two constraints each representing the conservation condition and the incompressible condition.

\[
\int dr \psi_i^2(r) = V \bar{\phi}_i, \quad (i = A, B, S) \\
\sum_{i=A,B,S} \psi_i^2(r) = 1
\]

where \( V \) is the volume of the system and \( \bar{\phi}_i \) is the spatial average of \( \phi_i(r) \). \( \bar{\phi}_S \) is the average volume fraction of solvent and \( \bar{\phi}_A, \bar{\phi}_B \) are given by the following equations.

\[
\bar{\phi}_A = f_A \bar{\phi}_{AB} \\
\bar{\phi}_B = f_B \bar{\phi}_{AB}
\]

where \( \bar{\phi}_{AB} \) is the average volume fraction of the AB diblock copolymer. \( \bar{\phi}_{AB} \) and \( \bar{\phi}_S \) satisfy the following equation.

\[
\bar{\phi}_{AB} + \bar{\phi}_S = 1
\]

Constraints eqs (5), (6) give the following terms for the free energy functional (4).

\[
F_{\text{constraints}} [\psi_A(r), \psi_B(r), \psi_S(r)] = \sum_i \int dr \frac{1}{2} [\lambda_i + \kappa(r)] [\psi_i^2(r) - \bar{\phi}_i] 
\]

where \( \lambda_i \) and \( \kappa(r) \) are the Lagrangian multipliers which correspond to the conservation and incompressible conditions, respectively.
3.2 Numerical Scheme

The free energy was minimized by evolving the \( \psi \)-field iteratively by using the steepest-descent method.

\[
\psi^{(\text{new})}_i(r) = \psi_i(r) - \omega [\mu_i(r) + \lambda_i \psi_i(r) + \kappa(r) \psi_i(r)]
\]

(11)

where \( \omega \) is positive constant and \( \mu_i(r) \) is the chemical potential defined as

\[
\mu_i(r) \equiv \frac{\delta F[\psi_A(r), \psi_B(r), \psi_S(r)]}{\delta \psi_i(r)}
\]

(12)

By substituting eq (4) into eq (12), we get the explicit form of the chemical potential (See Appendix B for detail).

We employed the time-splitting method and the ADI method \( [24] \) to update \( \psi^{(\text{new})}_i(r) \) from \( \psi_i(r) \) by eq (11).

\[
\begin{align*}
\psi^{(1)}_i(r) &= \psi_i(r) - \omega^{(1)} \left\{ \left[ \mu^{(1)}_i(r) + \frac{b^2}{3} \frac{\partial^2 \psi^{(1)}_i(r)}{\partial x^2} \right] - \frac{b^2}{3} \frac{\partial^2 \psi^{(1)}_i(r)}{\partial x^2} \right\} \\
\psi^{(2)}_i(r) &= \psi^{(1)}_i(r) - \omega^{(1)} \left\{ \left[ \mu^{(2)}_i(r) + \frac{b^2}{3} \frac{\partial^2 \psi^{(1)}_i(r)}{\partial y^2} \right] - \frac{b^2}{3} \frac{\partial^2 \psi^{(1)}_i(r)}{\partial y^2} \right\} \\
\psi^{(3)}_i(r) &= \psi^{(2)}_i(r) - \omega^{(1)} \left\{ \left[ \mu^{(3)}_i(r) + \frac{b^2}{3} \frac{\partial^2 \psi^{(2)}_i(r)}{\partial z^2} \right] - \frac{b^2}{3} \frac{\partial^2 \psi^{(2)}_i(r)}{\partial z^2} \right\} \\
\psi^{(4)}_i(r) &= \psi^{(3)}_i(r) - \omega^{(2)} \kappa(r) \psi^{(3)}_i(r) \\
\psi^{(\text{new})}_i(r) &= \psi^{(4)}_i(r) - \omega^{(3)} \lambda_i \psi^{(4)}_i(r) \\
\end{align*}
\]

(13-17)

where \( \omega^{(n)} \) is positive constant and \( \mu^{(n)}_i \) is the chemical potential calculated from \( \psi^{(n)}_i(r) \). The advantage of using the ADI method is that we can choose a large value for \( \omega \) compared with one used in the explicit method which we employed in our previous work \( [23] \). The evolution with eq (17) can be regarded as rescaling of the \( \psi \)-field to satisfy the conservation law (this is analogy to the wave function in quantum mechanics; we normalize the wave function to get probability density). Thus eq (17) was modified as follows.

\[
\psi^{(\text{new})}_i(r) = \frac{V \bar{\phi}_i}{\int dr \left[ \psi^{(4)}_i(r) \right]^2} \psi^{(4)}_i(r)
\]

(18)

We also evolved \( \kappa(r) \) as well.

\[
\kappa^{(\text{new})}(r) = \kappa(r) - \omega^{(4)} \left[ \psi^2_i(r) - \bar{\phi}_i \right]
\]

(19)

Eqs (13)-(16), (18) and (19) were solved iteratively to get the steady state structure. All simulations were started from the nearly homogeneous state with small Gaussian white noise and the periodic boundary condition was used. The evolution was conducted until the \( \psi \) field do not change anymore. This structure is not necessarily the equilibrium structure: in most cases it is a metastable structure. As our purpose is to search various metastable structures, we did not pursue to find the real minimum of the free energy.

The numerical scheme described above produces the equilibrium (or metastable) structure efficiently. For example, we can get 3 dimensional AB diblock copolymer vesicles (lattice points: 128×128×128, detail parameters are shown in the following section) starting from the homogeneous state in about 26 hours on a 3.0GHz Pentium 4 PC.

For the systems with small volume fraction of the block copolymer and/or small \( \chi \) parameter, spontaneous formation of the self-organized structure from the homogeneous state was not always successful. It is difficult to get the micellar structure by our scheme especially for these systems. Thus we used the following procedure.
We started the simulations from the nearly homogeneous state by using rather large γ parameter (for example $\gamma_{AB} = 1$) and/or large volume fraction (for example $\phi_{AB} = 0.1$). This gives a state which has a large density fluctuation after several hundreds iteration steps. We then switched $\gamma_{AB}$ and $\phi_{AB}$ to the target value and continued the simulation for several thousand iteration steps (about 2000 to 4000 in this work) to get the equilibrium state. Though arbitrary and artificial it may look, such procedure was needed in order to get the phase separated structure. In fact, without the procedure, we could not reproduce the phase separation in the region where the γ parameter or the volume fraction are small.

4 Result

4.1 AB Diblock Copolymer Solutions (AB Diblock Copolymer / C Solvent)

First we show the result of the simulation for the AB diblock copolymer solutions. We set the A monomer is solvent-philic and the B monomer is solvent-phobic (i.e. the γ parameter between the A and C monomers is small or negative, and that between the B and C monomers is large).

Figure 1 shows the result of the simulation. Here the surfactant is a medium sized block copolymer ($N_{AB} = 20$) with short solvent-philic part ($f_A = 1/3$) and long solvent-phobic part ($f_B = 2/3$). The other parameters are $N_C = 1, \gamma_{AB} = 0.1, \gamma_C = 0.9, \gamma_{AB} = 1, \gamma_{BC} = 1.75$, and $\gamma_{AC}$ are taken to be 0.5 (a), 0 (b) and -0.175 (c). The system size is $48b \times 48b \times 48b$ and the number of lattice points is $96 \times 96 \times 96$.

The figure demonstrates that the density functional method gives self organized structures spontaneously starting from a nearly homogeneous initial state. Various micellar structures – spherical micelles, cylindrical micelles, open bilayers (not closed membrane structures) and vesicles are observed. Notice that the micellar structure is not the same: there is a distribution of micellar size as well as the micellar structure. We believe that real micellar system will also have such distribution.

The morphological change shown in Figure 1 can be qualitatively understood as follows. As $\gamma_{AC}$ decreases, the affinity between the solvent and the solvent-philic part increases. Therefore the interfacial area between the micelles and solvent tends to increase. As a result, the micellar structure changes from spheres to cylinders and then to vesicles.

Figure 2 shows the 1 dimensional density profile of Figure 1(c). It is observed that AB diblock copolymer is strongly localized at the micellar structure (the vesicle) and the density of unimers are quite small.

To investigate the effect of the architecture of block copolymers, we fixed the parameter except for the block ratio and performed several simulations with different block ratio. The parameters are set to $N_{AB} = 20, N_C = 1, \gamma_{AB} = 0.1, \gamma_C = 0.9, s\gamma_{AB} = 1, \gamma_{BC} = 1.75, \gamma_{CA} = -0.175$, system size: $32b \times 32b \times 32b$, lattice points: $64 \times 64 \times 64$ and the simulations have been done for block ratio $f_B = 0, 0.1, 0.2, 0.3, 1/3, 0.4, 0.5, 0.6, 2/3, 0.7, 0.8, 0.9, 1$. The result is shown in Figure 3 It is seen that if the block ratio of the solvent-phobic subchain is too short (i.e., if $f_B < 1/3$), the block copolymer acts as the solvent-philic homopolymer. Thus the system is homogeneous and the micellar structure is not formed. As increasing the block ratio of the solvent-phobic subchain, spherical micelles and the cylindrical micelles are formed (the relation between the morphology of micellar structure and the block ratio is studied by Ohta and Nonomura for the strong segregation limit [25]). As increasing the block ratio further, the vesicles are formed. In this case the block ratio of solvent-phobic subchain is large, i.e. the block copolymer is so-called crew-cut block copolymer. If one increase the block ratio further, the block copolymer acts as the solvent-phobic homopolymer and causes macro phase separation to form droplets.

4.2 AB Diblock Copolymer / A Homopolymer Blends

We now study the AB diblock copolymer / A homopolymer blends. Like the case of solution, the AB diblock copolymer form micelles in the matrix of A homopolymers.
From the technical viewpoint, simulation of polymer blends is easier than the simulation of polymer solutions since strong segregation is easily achieved in polymer blends for small $\chi$ parameters: large $\chi$ parameter makes the interface sharper and causes numerical stability problems at the interface.

Figure 4 shows an example of the simulation result for a large system. Here the system involves $128 \times 128 \times 128$ lattice points (the system size is $64b \times 64b \times 64b$), and the parameters are set to be $N_{AB} = 20, N_A = 10, f_A = 1/3, f_B = 2/3, \chi_{AB} = 1, \tilde{\phi}_{AB} = 0.1, \tilde{\phi}_A = 0.9$. In this case, vesicles can be observed more clearly than Figure 4(c). This is considered to be due to the change of the strength of segregation (the segregation of this system is stronger than the system of Figure 1(c)).

Various self-organized structures can be formed depending on the parameters such as the block ratio $f_A, f_B$, the volume fraction $\phi_{AB}$ and the $\chi$ parameter $\chi_{AB}$. To study the relation between these parameters and the micellar structure, we conducted a simulation of smaller system which involves $64 \times 64 \times 64$ lattice points. The polymerization index for the AB diblock copolymer and the A homopolymer is set to $N_{AB} = 20, N_A = 10$, respectively.

Morphological change can be observed by chaining the parameters. Figure 5 shows the effect of the block ratio $f_A, f_B$. Other parameters are set to $\phi_{AB} = 0.1, \phi_A = 0.9, \chi_{AB} = 1$. If the B block is small (Figure 5a), $f_B = 1/3$, the diblock copolymer forms a spherical micelle which consists of inner core made of B block and the outer corona made of A block. As the fraction of the B block increases, the spherical micelles become unstable, and vesicles consisting of a bilayer of the block copolymers is formed. (Figure 5b), $f_B = 0.5$). The thickness of the B block in the bilayer increases with the increase of B block ratio. Finally, when $f_B$ becomes equal to unity, the macro-phase separation between A homopolymer and B homopolymer is observed. (Fig. 5d), $f_B = 1$). This behavior is just the same as one of the block copolymer solutions. Figure 6 shows the effect of $\tilde{\phi}_{AB}$, the volume fraction of diblock copolymers. Other parameters are set to $f_A = 1/3, f_B = 2/3, \chi_{AB} = 1$. As the volume fraction of the diblock copolymer increases, the micellar structures change from the spherical micelles to the cylindrical micelles and vesicles. Figure 7 shows the effect of $\chi_{AB}$ parameter between the monomer A and monomer B. Other parameters are set to $f_A = 1/3, f_B = 2/3, \phi_{AB} = 0.1, \phi_A = 0.9$. As the $\chi$ parameter increases, (i.e., as the antagonicity between the monomers A and B increases), the structures change from the spherical micelles to the cylindrical micelles and then to vesicles. This behavior is just like the case of the volume fraction change.

These results are considered to be consistent with the experimental results of Eisenberg et al. [26, 27, 1]. They studied the morphology of diblock copolymers in mixed solvent (water plus dioxane) for various block copolymer concentration and for various solvent composition, and observed the change of the micellar shape from sphere to cylinder and then to vesicles as the water content of the solvent increases. If one regard the change of the water content as the change of the $\chi$ parameter between the solvent and the subchain of block copolymer which forms core, our results are qualitatively in agreement with their experiments.

In order to demonstrate the similarity between the experimental results and our simulations, we conducted the simulation in the parameter space of $\phi_{AB}$ and $\chi_{AB}$. Fig. 8 shows the result. The figure is in qualitatively agreement with Fig. 6 in Ref. [26]. Note that our simulations was not done for large systems and the size of the simulation cell may affect the final micellar structure (the finite size effect or the effect of the periodic boundary conditions).

### 5 Discussion

The micellar structures, including vesicles can be formed for the AB diblock copolymer solutions by using the free energy model eq (1). The diblock copolymer density is dilute in our systems and the diblock copolymer strongly localized at the micellar structures (i.e. the system is the strong segregation). Note that such systems are difficult to treat by the previous density functional approaches. Our free energy model can handle these systems qualitatively correct and the simulation with our model is much faster than the real-space SCF simulation.

The dynamic vesicle formation process, however, cannot be discussed by our numerical scheme because our scheme does not satisfy the local conservation of mass. This is in contrast to the
particle methods (BD and DPD). Nevertheless it is instructive to study the process of the micellar formation based on our model.

The vesicle formation process for the AB diblock copolymer / A homopolymer blend by our scheme is shown in Figure 9 ($N_{AB} = 20, N_A = 10, f_A = 1/3, f_B = 2/3, \chi_{AB} = 1, \phi_{AB} = 0.1, \phi_A = 0.9$, system size: $32b \times 32b \times 32b$, lattice points: $64 \times 64 \times 64$, $\omega^{(1)} = 0.5$). It is observed that the nucleus of micellar structure is first formed by the association of block copolymers (the matrix polymer is expelled from the micellar structure at this stage). The micellar structure then grows taking solvent into its core from the surrounding, and finally the vesicle is formed.

This process is the same as that observed by He et al. in their 2 dimensional simulation using the SCF method. (They also used the non-conserving scheme for the evolution of the local density.) According to the scenario of He et al., the nucleus of micellar structures grows first. If the nucleus grows sufficiently large, the nucleus takes solvent into the core because the hydrophilic subchains localized at the large micelles are energetically unfavorable. Finally the micellar structure changes their shape from the sphere-like structure into shell-like structure and thus vesicles are formed.

Therefore our vesicle formation process is the same as one of He et al.. This agreement implies that the schemes which does not satisfy the local conservation can form vesicles easily compared with the schemes which is based on the dynamics and satisfy the local conservation (for example, the Cahn-Hilliard type TDGL equation or the dynamic SCF method). The dynamic vesicle formation process based on the continuous field model simulation is the future work.

6 Conclusion

We have shown that the self-organized structure of block copolymers in solvent can be predicted by the density functional theory using the free energy proposed in Ref. This is the first 3 dimensional simulation of vesicle formation by using the continuous field model. Since the theory can take into account of actual structure of polymers (degree of polymerization, block ratio, topological structure), it will be useful to understand and to predict the micellar structure of surfactant systems.

Appendix

A Form of Matrices $A_{ij}, C_{ij}$

The matrices $A_{ij}, C_{ij}$ for diblock copolymer is represented as follows.

$$A_{ij} = \frac{9}{N_{AB}^2 b^2 f_A f_B} \begin{bmatrix} f_B^2 & -f_A f_B \\ -f_A f_B & f_A^2 \end{bmatrix}$$

$$C_{ij} = \frac{1}{N_{AB}} \begin{bmatrix} \tilde{S}^{-1}_{AA} \left( \frac{3}{f_A} \right) - \frac{1}{f_A} \sqrt{3} f_A \\ -\frac{1}{4 f_A f_B} \tilde{S}^{-1}_{BB} \left( \frac{3}{f_B} \right) - \frac{1}{f_B} \sqrt{3} f_B \end{bmatrix}$$

where $\tilde{S}^{-1}(\xi)$ is the inverse matrix for the normalized scattering function matrix $\tilde{S}(\xi)$ for the ideal systems.

$$\sum_j \tilde{S}_{ij}(\xi) \tilde{S}_{jk}^{-1}(\xi) = \delta_{ik}$$

$\tilde{S}(\xi)$ is defined as follows.

$$\tilde{S}_{ij}(\xi) = \begin{bmatrix} \frac{2}{\xi^2} (e^{-f_A \xi} - 1 + f_A \xi) & \frac{1}{\xi^2} (e^{-f_A \xi} - 1)(e^{-f_B \xi} - 1) \\ \frac{1}{\xi^2} (e^{-f_A \xi} - 1)(e^{-f_B \xi} - 1) & \frac{2}{\xi^2} (e^{-f_B \xi} - 1 + f_B \xi) \end{bmatrix}$$

B Chemical Potential

The chemical potential for the system can be calculated by substituting eq (4) into eq (12). The chemical potential for the A, B subchains and S solvent is as follows.

\[
\mu_A(r) = \sum_{j=A,B} \int dr' 4 \sqrt{f_j} A_j \mathcal{G}(r - r') \psi_j(r')
+ 2f_A C_{AA} [2\psi_A(r) \ln \psi_A(r) + \psi_A(r)]
+ 4 \sqrt{f_A f_B} C_{AB} \psi_B(r)
- \frac{b^2}{3} \nabla^2 \psi_A(r)
+ \sum_{j=A,B,S} 2\chi_{A,j} \psi_j^2(r) \psi_A(r)
\]

(24)

\[
\mu_B(r) = \sum_{j=A,B} \int dr' 4 \sqrt{f_j} A_j \mathcal{G}(r - r') \psi_j(r')
+ 2f_B C_{BB} [2\psi_B(r) \ln \psi_B(r) + \psi_B(r)]
+ 4 \sqrt{f_A f_B} C_{AB} \psi_A(r)
- \frac{b^2}{3} \nabla^2 \psi_B(r)
+ \sum_{j=A,B,S} 2\chi_{B,j} \psi_j^2(r) \psi_B(r)
\]

(25)

\[
\mu_S(r) = \frac{2}{N_s} [2\psi_S(r) \ln \psi_S(r) + \psi_S(r)]
- \frac{b^2}{3} \nabla^2 \psi_S(r)
+ \sum_{j=A,B,S} 2\chi_{B,j} \psi_j^2(r) \psi_S(r)
\]

(26)

Note that \(\mu_i(r)\) contains the Laplacian term \(-\frac{b^2}{3} \nabla^2 \psi_i(r)/3\) for all \(i\). Thus the evolution equation, eq (11), can be expressed as

\[
\psi_i^{(\text{new})}(r) = \psi_i(r) + \frac{\omega b^2}{3} \nabla^2 \psi_i(r) + \ldots
\]

(27)

As mentioned before, eq (24) can be solved stably by using implicit scheme (the ADI scheme, in this work), in analogy to the diffusion equation.

Figure 1: Micellar structures of the AB diblock copolymer solutions (AB diblock copolymer / C solvent blends) with different $\chi$ parameters. The system size is $48b \times 48b \times 48b$ (96 $\times$ 96 $\times$ 96 lattice points). Parameters are set to $N_{AB} = 20, N_C = 1, \bar{\phi}_{AB} = 0.1, \bar{\phi}_C = 0.9, \chi_{AB} = 1, \chi_{BC} = 1.75, f_A = 1/3, f_B = 2/3$. (a) $\chi_{AC} = 0.5$, (b) $\chi_{AC} = 0$, (c) $\chi_{AC} = -0.175$. The gray surfaces are isodensity surfaces for $\phi_B(r) = 0.5$. 
Figure 2: Density profile of an AB diblock copolymer vesicle. The parameters used are the same as Figure 1(c). The 1 dimensional density profile (right) is the profile along the black line in the 3 dimensional isosurface data (left).
Figure 3: Phase diagram of AB diblock copolymer solutions. (a) $f_B = 1/3$, (b) $f_B = 0.5$, (c) $f_B = 0.6$, (d) $f_B = 1$. $N_{AB} = 20, N_C = 1, \bar{\phi}_{AB} = 0.1, \bar{\phi}_C = 0.9, \chi_{AB} = 1, \chi_{BC} = 1.75, \chi_{CA} = -0.175$, system size: $32b \times 32b \times 32b$, lattice points: $64 \times 64 \times 64$.

Figure 4: A result of the simulation for the AB diblock copolymer / A homopolymer blend. The system size is $64b \times 64b \times 64b$ which involves $128 \times 128 \times 128$ lattice points. The parameters of polymers are $N_{AB} = 20$, $N_A = 10$, $f_A = 1/3$, $f_B = 2/3$, $\chi_{AB} = 1$. The volume fractions are $\bar{\phi}_{AB} = 0.1$, $\bar{\phi}_A = 0.9$. The gray surfaces are isodensity surfaces for $\phi_B(r) = 0.5$. 
Figure 5: Results of simulations with different block ratios. The system size is $32b \times 32b \times 32b$. $N_{AB} = 20, N_A = 10, \bar{\phi}_{AB} = 0.1, \bar{\phi}_A = 0.9, \chi_{AB} = 1$. (a) $f_B = 1/3$, (b) $f_B = 0.5$, (c) $f_B = 2/3$, (d) $f_B = 1$. The gray surfaces are isodensity surfaces for $\phi_B(r) = 0.5$. 
Figure 6: Results of simulations with different volume fractions. The system size is $32b \times 32b \times 32b$. $N_{AB} = 20, N_A = 10, f_A = 1/3, f_B = 2/3, \chi_{AB} = 1$. (a) $\bar{\phi}_{AB} = 0.025$, (b) $\bar{\phi}_{AB} = 0.0525$, (c) $\bar{\phi}_{AB} = 0.075$, (d) $\bar{\phi}_{AB} = 1$. The gray surfaces are isodensity surfaces for $\phi_B(\mathbf{r}) = 0.5$. 
Figure 7: Results of simulations with different $\chi$ parameters. The system size is $32b \times 32b \times 32b$. $N_{AB} = 20, N_A = 10, f_A = 1/3, f_B = 2/3, \phi_{AB} = 0.1, \phi_A = 0.9$. (a) $\chi_{AB} = 0.0475$, (b) $\chi_{AB} = 0.525$, (c) $\chi_{AB} = 0.75$, (d) $\chi_{AB} = 1$. The gray surfaces are isodensity surfaces for $\phi_B(r) = 0.5$. 

17
Figure 8: Phase diagram of AB diblock copolymer / A homopolymer blend. The plotted symbols (circles, squares, etc.) correspond to the result of simulations with various $\chi_{AB}$ and $\phi_{AB}$. The bilayer phase means open, disk-like micelles (actually it is observed by experiment [27]).
Figure 9: Snapshot of vesicle formation process for the AB diblock copolymer / A homopolymer blend. Number of iteration step = 0, 470, 500, 530, 990 for (a), (b), (c), (d), (e), respectively. $N_{AB} = 20, N_A = 10, f_A = 1/3, f_B = 2/3, \chi_{AB} = 1, \bar{\phi}_{AB} = 0.1, \bar{\phi}_A = 0.9$, system size: $32b \times 32b \times 32b$, lattice points: $64 \times 64 \times 64$ (The parameters are the same as Figure 4 except for the system size.)
