Reverse Rotations in the Circularly-Driven Motion of a Rigid Body

Fernando Parisio
Departamento de Física, Universidade Federal de Pernambuco, 50670-901, Recife, PE, Brazil and Instituto de Física, Universidade Federal de Alagoas, 57072-970, Maceió, AL, Brazil

We study the dynamical response of a circularly-driven rigid body, focusing on the description of intrinsic rotational behavior (reverse rotations). The model system we address is integrable but nontrivial, allowing for qualitative and quantitative analysis. A scale free expression defining the separation between possible spinning regimes is obtained.

PACS numbers: 45.40.-f, 45.20.dc, 02.30.Ik

Nontrivial effects may arise in the realm of integrable classical mechanics. The most recent manifestation of this fact is the refreshed interest in the dynamics of sliding bodies [1]. In particular, the work by Farkas et al [2], an investigation on the frictional coupling between translational and rotational motions, has deserved attention, being followed by a dozen of papers on related topics [3]. Most of these previous work address the influence of friction in the free (not driven) dynamics of disks. In the present paper we deal, in a sense, with a complementary problem, namely, that of frictionless dynamics of a forced rigid body (RB). More specifically, we study the dynamical response of RB's submitted to rotational driving forces (in a way that will become clear below), focusing on the appearance of reverse rotations. Generally speaking, a reverse rotation occurs when a system, or part of it, is forced to rotate counterclockwise and its intrinsic angular degree of freedom develops a clockwise motion, or vice-versa. This terminology has been recently used in the literature to designate unexpected rotational behavior of a cylinder inside a rotating drum filled with a viscous fluid [4]. Related, though more intricate phenomena have been reported in the chaotic response of a parametrically excited pendulum [5], and in tests of printing machinery of journals [6]. Therefore, reverse rotations are a general behavior in diverse physical systems. In what follows we propose a simple mechanical model to investigate this effect in an analytical way.

Our model system is schematically shown in Fig. 1(a). It consists of a uniform disk of mass $m$ and radius $R$ resting on a horizontal frictionless surface. We consider a disk only for convenience, the following reasoning is valid for an arbitrary RB (this point shall be discussed at the end of the manuscript). The system is then submitted to an external horizontal force $F$, provided by a driving apparatus, through a thin rod attached to a fixed point ($P$) on the disk, around which the whole body can rotate freely. The driving apparatus takes the disk from rest and makes the point $P$ follow a uniform circular trajectory of radius $d$ around a fixed origin ($O$) with angular frequency $\omega$ (see Fig. 1(b)). For definiteness we assume the rotation to be counterclockwise, and without loss of generality we use a coordinate system such that the point $P$ lies in the positive $x$-axis at $t = 0$. For later times we denote the position vector of $P$ by $\mathbf{d}$ and the vector locating the center of mass ($CM$) by $\mathbf{r}$. Since the disk is assumed to be perfectly rigid, $P$ is always a distance $l$ apart from $CM$. The relative position of these two points is given by the vector $\mathbf{l}$, as shown in Fig. 1(b). Finally, the angle between the $x$-axis and the line connecting $CM$ and $P$ is denoted by $\phi$. The variables $\mathbf{r}$ and $\phi$ completely specify the position of the disk.

The main goal of this work is to answer the following question: Which range of initial angles $\phi_0$ and parameters $m$, $\omega$, $R$, $l$, and $d$, lead to a clockwise rotation of the disk around $P$, if this is possible at all? The well-posedness of this question shall become evident soon. Since the point $P$ itself is being forced in the counterclockwise direction, such a dynamical response characterizes a reverse rotation (decreasing $\phi(t)$ on average).

According to our definitions, we have $\mathbf{d} = d \cos(\omega t) \mathbf{x} + d \sin(\omega t) \mathbf{y}$, where $d$ can take any fixed value in the interval $(0, \infty)$. The vector $\mathbf{l}$ linking $CM$ to $P$ is given by $\mathbf{l} = l \cos \phi \mathbf{x} + l \sin \phi \mathbf{y}$, with $0 < l \leq R$. The position of $CM$ is denoted by $\mathbf{r} = x \mathbf{x} + y \mathbf{y}$. These three vectors must satisfy $\mathbf{r} + \mathbf{l} = \mathbf{d}$, which provides two holonomic constraints: $x = d \cos(\omega t) - l \cos \phi$, and $y = d \sin(\omega t) - l \sin \phi$.

One initially cope with the problem without being concerned with the question of how the disk came from rest to motion. This point shall be addressed later. Suppose that $F_c$, unknown a priori, is the constraint force that keeps the circular trajectory of $P$. This force is assumed to be provided by a robust apparatus in the sense that the circular path is not affected by the iner-
the disk. The equations of motion for the \( CM \) degrees of freedom read \( F_{c,x} = m\ddot{x}, \ F_{c,y} = m\ddot{y} \). The Newton’s Second Law for the angular coordinate is given by \( \tau_c = I \times F_c = I_{CM} \dot{\phi} \hat{z}, \), i.e.,

\[
mI(\cos \phi \ddot{y} - \sin \phi \ddot{x}) = I_{CM} \ddot{\phi},
\]

where \( I_{CM} \) is the inertia moment of the disk with respect to the center of mass \[7\]. By using the holonomic constraints we find \( \ddot{x} = l \sin \phi \ddot{\phi} + l \cos \phi \frac{d^2 \phi}{dt^2} - \omega^2 \cos(\omega t) \) and \( \ddot{y} = -l \cos \phi \ddot{\phi} + l \sin \phi \frac{d^2 \phi}{dt^2} - \omega^2 \sin(\omega t) \), one can, therefore, decouple the angular equation of motion, which becomes:

\[
\ddot{\phi} - \frac{mld\omega^2}{I_P} \sin(\phi - wt) = 0,
\]

where \( I_P = I_{CM} + ml^2 \). As expected, the uniform plane rotation generates an effective gravity. We now proceed to the following change of variables: \( \theta = \phi - \omega t + \pi \), implying \( \dot{\theta} = \dot{\phi} - \omega \) and \( \ddot{\theta} = \ddot{\phi} \). This change transforms Eq. \[2\] into the simple pendulum equation \( \ddot{\theta} + \frac{mld}{I_P} \omega^2 \sin \theta = 0 \). Thus, we see that the time dependence of \( \phi \), the physically relevant variable, is given by a combination of pendular and uniform motions (plus a constant additional factor),

\[
\phi(t) = \theta_{\text{pendulum}}(t) + \omega t - \pi.
\]

Note that solution \[3\] automatically yields \( x(t), y(t) \), and \( F_c(t) \). It also implies that we have a hidden constant of the motion corresponding to the mechanical energy of the auxiliary pendulum (we shall use this terminology to refer to the pendular term in the solution \[3\]).

\[
\mathcal{E} = \frac{1}{2} I_P \dot{\theta}^2 + 2mld\omega^2 \sin^2(\theta/2),
\]

where the potential energy is set to zero in its lower position. In terms of initial conditions of the original variable we have

\[
\mathcal{E} = \frac{1}{2} I_P (\dot{\theta}_0 - \omega)^2 + 2mld\omega^2 \cos^2(\phi_0/2).
\]

By inspecting solution \[3\] we note that reverse rotations of the disk are possible only when \( \theta_{\text{pendulum}} \) describes a motion of rotation instead of libration, that is, the mechanical energy of the auxiliary pendulum must satisfy \( \mathcal{E} > 2mld\omega^2 \) in negative pendular cycles. Relation \[4\] together with the equality \( \mathcal{E} = 2mld\omega^2 \) define the curves that separate libration and rotation of variable \( \theta \) in the space of initial conditions \( (\phi_0, \dot{\phi}_0) \). One finds that initial conditions in between the curves

\[
\dot{\phi}_0 = \omega \left[ 1 \pm 2 \sqrt{\frac{mld}{I_P}} \sin(\phi_0/2) \right]
\]

lead to libration of \( \theta \), and thus, to normal rotation of the disk. Of course, not all points that lie outside this region lead to reverse behavior. The pendular rotation must be clockwise with an angular frequency larger than \( \omega \), in order to make \( \phi(t) \) a decreasing function of \( t \), on average. The condition for reverse rotation then reads

\[
T = \sqrt{\frac{2I_P K}{\mathcal{E}}} \left( \omega \sqrt{2mld \mathcal{E}} \right) < \frac{2\pi}{\omega},
\]

for clockwise pendular cycles of period \( T \), where \( K \) denotes the complete elliptic function of first kind. In the regions where \( T \) equals \( 2\pi/\omega \), the constant \( \mathcal{E} \) satisfies the transcendental equation

\[
K \left( \omega \sqrt{2mld \mathcal{E}} \right) = \frac{\pi}{\omega} \sqrt{\frac{\mathcal{E}}{2I_P}}.
\]

Using this prescription and Eq. \[4\] we manage to select the initial conditions \( (\phi_0, \dot{\phi}_0) \) that lead to reverse and normal rotations. These regimes are separated by the curve

\[
\dot{\phi}_0 = \omega - \sqrt{\frac{2\mathcal{E}}{I_P} - \frac{4mld\omega^2}{I_P} \cos^2(\phi_0/2)},
\]

where \( \mathcal{E} \) stands for the solution of Eq. \[4\]. The root with a plus sign was discarded because it is related to positive pendular rotations. We name the above defined curve a synchronization line because initial conditions on it develop neither normal nor reverse rotation, for the angular frequency of \( \theta \) coincides with \( \omega \) and, therefore, the time evolution of \( \phi \) averages to a constant value.

At this point we address the problem with static initial conditions. This is the most interesting situation, since it is expected that high enough clockwise initial velocities \( \dot{\phi}_0 \) trivially lead to reverse rotations. We note, however, that \( \ddot{x}, \ddot{y}, \phi \) never vanish simultaneously, and, thus, the kinetic energy of the disk \( K = m\ddot{x}^2/2 + m\ddot{y}^2/2 + I_{CM} \ddot{\phi}^2/2 = ml^2\omega^2/2 + (I_P\omega^2/2 + mld\omega - \mathcal{E}/\omega) \dot{\phi}^2/2 + I_P \dot{\phi}^2/2 \) is nonzero for all times. It is clear that the force \( F_c \), alone is not compatible with static initial conditions. In order to encompass these conditions, we assume that an impulsive force acts on the disk, taking it from rest to motion in a time scale much shorter than any other in the problem, e. g. \( 2\pi/\omega \). This is a realistic assumption when we have a table top engine driving a light body. More explicitly, we suppose that the force can be split into two parts

\[
F = \left\{ \begin{array}{ll}
F_0 & \text{for } t \in [0^-, 0^+] \\
F_c & \text{for } t > 0^+
\end{array} \right.
\]

where \( F_0 \) denotes the impulsive force that acts during an arbitrarily small time interval centered at \( t = 0 \). In the limiting case we have a delta function, which we initially write in generic form as \( F_0 = \delta(t) (\alpha \dot{x} + \beta \dot{y}) \), where \( \alpha \) and \( \beta \) have dimension of momentum. These constants are to be determined by the motion we know the force \( F_0 \) causes to the disk. More specifically, we know that, immediately after its application, to fit the \( F_c \) prescription, the point \( P \) must acquire a velocity

\[
\nu_P(0^+) = \omega d \dot{\gamma}.
\]
The equations of motion in the infinitesimal interval $[0^-, 0^+]$ are $m\ddot{x} = \alpha \dot{\phi}(t)$, $m\ddot{y} = \beta \dot{\phi}(t)$, and $I \cos \phi \dot{\beta}(t) - I \sin \phi \dot{\delta}(t) = I_{CM} \ddot{\phi}$. Integrating one obtains the velocities soon after the application of $F_0$

$$\dot{x}(0^+) = \frac{\alpha}{m}, \quad \dot{y}(0^+) = \frac{\beta}{m}, \quad \dot{\phi}(0^+) = \frac{l}{I_{CM}} (\beta \cos \phi_0 - \alpha \sin \phi_0),$$

(9)

where, here, the static initial conditions were employed: $\dot{x}(0^-) = 0$, $\dot{y}(0^-) = 0$, and $\dot{\phi}(0^-) = 0$. We also used $\phi(0^-) = \phi(0^+) = \phi_0$ (since the impulsive force causes no discontinuity in coordinates). The velocity of $P$ at any time is given by $\mathbf{v}_P = \dot{x} + \dot{l} = (\dot{x} - l \dot{\phi} \sin \phi) \hat{x} + (\dot{y} + l \dot{\phi} \cos \phi) \hat{y}$. Therefore, the initial velocity as a function of $\alpha$ and $\beta$ is

$$\mathbf{v}_P(0^+) = \left[ \frac{\alpha}{m} - \frac{l^2}{I_{CM}} \sin \phi_0 (\beta \cos \phi_0 - \alpha \sin \phi_0) \right] \hat{x} + \left[ \frac{\beta}{m} + \frac{l^2}{I_{CM}} \cos \phi_0 (\beta \cos \phi_0 - \alpha \sin \phi_0) \right] \hat{y}. $$

By applying the consistency condition \cite{8} we obtain a pair of equations, involving $\alpha$ and $\beta$, whose solution is

$$\alpha = \frac{\omega dm l^2}{P} \sin \phi_0 \cos \phi_0, \quad \beta = md \omega \left( 1 - \frac{m l^2}{P} \cos^2 \phi_0 \right).$$

We then found the impulsive force that is consistent with the subsequent evolution of the system. Substituting the above results in the last equation in \cite{10} we obtain a quite simple relation between the initial angle $\phi_0$ and the initial velocity $\dot{\phi}_0$ (where we suppress the argument $0^+$). Given the initial angle of the static disk, the angular velocity it acquires immediately after the driving apparatus is turned on is

$$\dot{\phi}_0 = \frac{md \omega}{P} \cos \phi_0. \quad (10)$$

Only pairs $(\phi_0, \dot{\phi}_0)$ related through this expression are valid initial conditions. We are now in position to show the relevant regions and curves in the space of initial conditions. In Fig. 2(a) we show the normal (blank) and reverse (dotted) regions in the space $(\phi_0, \dot{\phi}_0)$, separated by the synchronization line (grey curve). The black line represents the possible initial conditions as given by \cite{10}. We used the following parameters: $\omega = 6$ rad/s ($\nu \sim 1$ Hz), $m = 100$ g, $R = 10$ cm, $l = 7$ cm, and $d = 10$ cm. For these values, the constant of the motion that satisfies Eq. (5) is $\dot{\mathcal{E}} \approx 0.0543$ J. We see that, for theses parameters, no reverse rotations can occur (the black curve do not reach the dotted region). In contrast, if we set $d = 40$ cm, keeping the other parameters (leading to $\dot{\mathcal{E}} \approx 0.2017$ J), we obtain the result displayed in Fig. 2(b), where it is clear (the grey and black curves cross each other) that reverse rotations take place for an interval of initial angles centered in $\phi_0 = \pi$. The three initial conditions marked with a square, a circle, and a triangle represent the possible regimes: normal rotation, synchronization, and reverse rotation. The time evolution of $\phi$ for these three conditions is shown in Fig. 3. The corresponding initial angles in radians are: $\phi_0 \approx 2.20$ (black), $\phi_0 \approx 2.44$ (grey), and $\phi_0 \approx 2.68$ (light grey). Notice that in the black curve, e. g., we have normal and reverse instantaneous motions depending on the instant we record the velocity $\dot{\phi}$. The results presented in Fig. 2 refer to the global behavior of $\phi$.

It is possible to establish in a more precise way which initial configurations lead to reverse rotations. First we note that the range of initial angles that lead to reverse behavior is bounded by the intersections of the synchronization line \cite{11} and the initial condition curve \cite{10}.
These boundary angles are given by

$$\cos^2 \phi_0^{(b)} = \frac{I_P^2}{(m dl \omega^2)^2} \left( \frac{2 \tilde{\omega}^2}{I_P^2} - \frac{2 ml dl^2 \omega^2}{I_P^2} - \omega^2 \right).$$

(11)

Since $0 \leq \cos^2 \phi_0^{(b)} \leq 1$, in order to get reverse rotations we must have

$$2 ml dl + I_P < \frac{2 \tilde{\omega}^2}{\omega^2} < \frac{1}{I_P} (I_P + ml dl)^2,$$

(12)

where we have a condition imposed on $\tilde{\omega} = \tilde{E}(m, d, l, I_P, \omega)$. Let us analyze the limiting cases: $\frac{2 \tilde{\omega}^2}{\omega^2} = 2 ml dl + I_P$ and $\frac{2 \tilde{\omega}^2}{\omega^2} = \frac{1}{I_P} (I_P + ml dl)^2$. Substituting these expressions in the transcendental equation (5) we obtain relations involving a single parameter, $K \left( \sqrt{\frac{2 \omega}{\sigma + 2}} \right) = \frac{\pi}{2} \sqrt{\sigma + 1}$ and $K \left( \frac{2 \sqrt{2 \omega}}{\sigma} \right) = \frac{\pi}{4} (\sigma + 2)$, respectively, with $\sigma = 2 ml dl / I_P$. The first equation has only the solution $\sigma = 0$, which is physically trivial, implying that the left-hand side of the inequality (12) is always fulfilled. The second equation, besides $\sigma = 0$, presents the solution $\tilde{\sigma} \approx 2.523$. Thus initial configurations obeying $2 ml dl / I_P = \tilde{\sigma}$, separate regions where reverse rotation is possible from regions where only normal rotations can occur. This condition involves only the relative scales $D = d / R \in (0, \infty)$ and $L = l / R \in (0, 1)$ and, in the case of a disk, reads

$$D = 0.631 L^{-1} + 1.261 L.$$

(13)

The above result is universal, in the sense that it is valid for any $m$ and $\omega$, and is independent from the absolute scales $R$, $l$, and $d$. As indicated in Fig. 4 initial geometrical configurations located below the curve (13) always lead to normal behavior, while configurations above it may enable reverse rotations, depending on the initial angle $\phi_0$ (the precise values of $\phi_0$ are given by Eq. (11)). We also note that there is a value of $d$ below which no reverse rotation occur. It is given by $D_{\text{min}} = \tilde{\sigma} / \sqrt{2}$, that is, $d_{\text{min}} = 1.784 R$. For $L > 0.5$, variations in this parameter produce virtually no change in $D$, which becomes the only relevant parameter to define the possible regimes of the system (see the “plateau” in Fig. 4).

We stress that the obtained results are very general since we used the particular form of $I_P$ only to obtain Eq. (13). For an arbitrary RB we have $I_P = ml^2 + \gamma m R^2$, where $\gamma$ is a number and $R$ is a characteristic scale. For the disk we have $\gamma = 1/2$ and $R = R$, while for a rectangular plate of sides $a$ and $b$ we have $\gamma = 1/12$ and $R = \sqrt{a^2 + b^2}$. The general form of Eq. (13) is

$$D = \frac{\tilde{\sigma}}{2} (\gamma L^{-1} + L),$$

(14)

with $D = d / R$ and $L = l / R$, for $R \neq 0$. We note that in the “degenerate” case of a point mass connected by a massless rod to the pivotal point, obtained from the

![FIG. 4: Configurations located above the curve may develop reverse rotations. Below the curve only normal rotation is possible.](image-url)

disk by taking $R = 0$, we get $\sigma = 2d/l$ and the reverse condition becomes a one-parameter relation $d/l > 1.261$.

We investigated reverse rotations in the circularly-driven motion of a RB whose intrinsic angular degree of freedom was shown to evolve according to a combination of pendular and uniform motions. This enabled the complete determination of the initial configurations that lead to reverse behavior (Eq. (12)). In addition a scale free, purely geometrical relation, defining the regions were reverse rotation is possible was obtained (Eq. (14)). The effects of friction, assumed to be negligible in this work, may play an interesting role. The friction generated in the small contact area connecting the thin rod and the RB gives an extra torque (but no net force). This may be the only friction in the problem if we assume that the RB is kept in the horizontal position solely by the rod. It may also be of interest to consider the system immersed in a viscous fluid. This would make our apparatus very similar to a bioreactor for tissue growth. It seems that the influence of the regime of intrinsic rotation of the tissue construct (our disk) is yet to be analyzed. These pending issues are presently under investigation.
