Abstract

We report a case of hemoglobin (Hb) Willamette (β51 Pro → Arg) in the Hematology Department of a tertiary hospital in Fortaleza, Northeast of Brazil. A literature review of the cases described in health sciences databases using as a descriptor Hb Willamette was performed, revealing 12 reported cases, of which only one presented with anemia. Herein, we describe a case of a female 29 years old, with hemoglobinopathy Willamette presenting clinically with anemia, having the lowest hemoglobin rate of the published cases. The relatives of the patient were evaluated and the patient’s mother corresponded to the first description of the association between Hb Willamette and HbC. Among the hemoglobinopathies, hemoglobin Willamette is an extremely rare disease; therefore it is important to analyze its clinical and laboratory manifestations for an accurate diagnosis and assessment of potential interactions with other genetic variants.

Case Report

Woman, 29 years old, born in Fortaleza, Brazil, referring history of anemia since childhood. The patient reported episodes of breathlessness associated with asthma, as well as malaise, asthena and difficulty concentrating which has worsened since 2010, when she sought medical assistance and was diagnosed with Hashimoto’s disease. She was referred to the hematology department of a tertiary hospital for persistent anemia, despite levithroxine replacement therapy. Her previous history revealed hypertrophic allergic rhinitis, bronchial asthma and hypothyroidism in use of levithroxine. Laboratory tests: hemoglobin: 8.4 g/dL, hematocrit: 23.4%, mean corpuscular volume: 75.0 fL, white blood cell count: 9745/mm³, platelet count: 384×10⁹/L, reticulocyte count: 4.8%, peripheral smear featuring anisocromia, microcytosis and polychromasia, with normal serum iron, transferrin saturation index and ferritin.

Study of hemoglobin by high-performance liquid chromatography (HPLC): HbA: 54.4% HbF: 0% HbA2: 2.5%. The chromatographic profile was suggestive of Hb Willamette in heterozygosis (Figure 1) and a mutation survey for HbS by molecular analysis study (PCR-RFLP) was negative.

Patient’s parents were also investigated for mutated Hb with HPLC. Father Result: HbA: 97.5%, HbF: 0% Hb A2: 2.5%. Mother Result: HbF: 0%, HbA2: 0%, HbS: 55.1%, HbC: 41.0%. The chromatographic profile of the mother revealed Hb Willamette as heterozygosis, the study by technique of molecular analysis (PCR-RFLP) showed no mutations for HbS, but Mutation for HbC.

This paper has been approved by an ethical committee and thus meets the standards of the Declaration of Helsinki.

Discussion

In 1976, as a result of a sickle cell disease screening program, a variant of hemoglobin with the same electrophoretic mobility of HbS was identified in three generations of an African-American family. Functional studies of hemoglobin showed the presence of arginine in the proline in position 51 residue of the abnormal β chain, and thus hemoglobin identified as Hb Willamette (β51 D2 Pro → Arg). Seven articles were found in the search for Hb Willamette in the PubMed database. From the total of seven publications, three reported the presence of new cases of mutation. Three other citations to Hb Willamette were found in SciVerse ScienceDirect database.

The three articles reporting the presence of twelve new cases of hemoglobinopathy...
also exhibited their structural description, and the successful use of the methods of electrospray mass spectrometry to identify variant Hb. Another paper assesses the structure of Hb Willamette through Activated Dissociation Collision and mass spectrometry. There are also reports of Hb variant in a review paper on unstable hemoglobins, and as a note for the advent of its discovery in another journal.

As to the heritability and hematologic workup, the study of University of Oregon Health Sciences Center disclosed the presence of a heterozygous affected family member in each of the three generations analyzed. The patients did not have anemia, splenomegaly, history of jaundice, cholelithiasis, reticulocytes or other clinical evidence of significant hematologic abnormalities, except the presence of target red blood cells.

In 1981, three cases in China were published describing the structural analysis of the abnormal hemoglobin molecule. There were also identified four relatives of these patients with the mutation. In a female patient, 10 years, anemia was diagnosed, which consisted of a new finding in relation to the series of American cases.

In 1983, another case was diagnosed with Hb in Willamette woman, 15 years old, black, Cuban, assessed at the Hematology Institute of Havana, where it was referenced by the diagnosis of acute lymphoblastic leukemia. The variant found was also present in her father.

As in the first report, hematologic abnormalities were not found with the exception of target cells in the peripheral blood smear. The instability test was slightly positive, as reported in the American family, however Heinz bodies were found after three hours’ incubation at 37°C in the Cuban study, finding absent in the American study. The Cuban authors highlighted the possibility that the discrepancy was due to differences in efficiency of various lots of coloring dyes, which can be considerable. Furthermore, the percentage of hemoglobin variant determined by DEAE-Sephadex chromatography method was 35% in two patients.

In the case reported, it is possible to observe anemia in association with Hb Willamette (Hb=8.4 g/dL). There was no clinical evidence of jaundice, splenomegaly and cholelithiasis, but the patient had the lowest Hb rates and the higher reticulocyte count between the published cases. Among the hemoglobinopathies, Hb Willamette is extremely rare, and may present with hemolytic anemia, due to its high reticulocyte index and RBC target, although often the patient is asymptomatic. Due to microcytosis an assessment for sideroblastic anemia on the basis of bone-marrow examination with Prussian blue stain was made with negative result. The percentage of Hb variant surpasses those described in previous articles, Willamette Hb=44.9% in the proband and Hb Willamette=55.1% in the mother. In addition, the mother of the patient corresponds to the first description of an association between Hb Willamette and HbC.

The description of sex, RBC, MCV, RETIC and relative amount of Hb Willamette of patients already detailed in the literature and presented in this paper can be observed in Table 1.

### Conclusions

Indeed, given the diversity of hemoglobin variants found in the population, an accurate laboratory diagnosis, able to elucidate possible interactions between genetic variants is necessary. The correct diagnosis is essential for treatment strategies and genetic counseling.
