ABSTRACT. Endogenous concentrations of IAA and ABA in the peel, pulp, seed, and abscission zone of mature ‘Valencia’ oranges [Citrus sinensis (L.) Osbeck] were determined by high-performance liquid chromatography and enzyme-linked immunosorbent assay from early November 1998 to mid-June 1999. Ethylene production of mature ‘Valencia’ oranges during the same period was determined by gas chromatography. IAA concentrations in the pulp and seed were three to five times lower than those in the peel over the 7-month observation period. IAA concentration in the abscission zone and peel was high from late April to mid-May, the period of less responsiveness to abscission chemicals. ABA concentration in the pulp was low over the entire observation period. ABA concentration in the abscission zone and peel was low during the less responsive period. Ethylene production was always low except for a slight increase during late December and early February. The IAA to ABA ratio was high in the fruit abscission zone during the less responsive period. Fruit detachment force of CMN–pyrazole-treated fruit was positively correlated with the ratio of endogenous IAA to ABA or endogenous IAA, but negatively to endogenous ABA in the fruit abscission zone. These data suggest the balance between IAA and ABA in the fruit abscission zone may be an important factor in determining sensitivity and thereby the response of mature ‘Valencia’ orange fruit to abscission chemicals. Chemical names used: abscisic acid (ABA); indole-3-acetic acid (IAA); 5-chloro-3-methyl-4-nitro-1H-pyrazole (CMN–pyrazole).

Most of the ‘Valencia’ oranges (Citrus sinensis) grown in Florida are used for processing and are harvested from early April through June (Wilson et al., 1981). Abscission chemicals can effectively reduce detachment force of mature ‘Valencia’ orange fruit and promote fruit abscission from mid-February through April. Then there is a period of 2 to 4 weeks during which the response of mature fruit to abscission chemicals is markedly reduced. Abscission chemicals become effective again after this period (Hartmond et al., 2000a; Holm and Wilson, 1976, 1977; Wheaton et al., 1977). However, little is known about the factors responsible for the less responsive period.

Oranges are nonclimacteric fruit and mature fruit abscise only at the abscission zone in the calyx (Brown, 1997; Goren, 1993). Endogenous plant hormones are involved in fruit abscission. The concentration of endogenous auxin in the abscission zone must decrease below a certain threshold to promote abscission (Osborne, 1989). In oranges, endogenous auxin and ethylene are two major hormones controlling the fruit or leaf abscission process (Goren, 1993). Application of 2,4 dichlorophenoxyacetic acid (2,4-D), a synthetic auxin, effectively reduced preharvest drop of orange fruit (Gardner et al., 1950; Zur and Goren, 1977). Sprays of abscisic acid (ABA) at 200 mg·L⁻¹ enhanced both ethylene production and fruit loosening of mature ‘Valencia’ oranges induced by the abscission chemical cycloheximide (CHI) (Cooper and Henry, 1972). Using explants of ‘Pineapple’ orange fruit and ‘Valencia’ orange fruit, Rasmussen (1974) found that ABA introduced through the stem was more effective than spray application in promoting cellulase activity and reducing fruit detachment force. During the harvest season, new flushes, young fruit for the following year’s crop, and roots grow rapidly. These young tissues are rich sources of endogenous plant hormones (Goldschmidt, 1976; Hofman, 1990; Plummer et al., 1991). Therefore, it has been speculated that endogenous plant hormones from these young tissues account for the reduced response of mature fruit to abscission chemicals in ‘Valencia’ oranges (Holm and Wilson, 1976; Rasmussen, 1973; Wheaton et al., 1977).

In a companion paper, we investigated seasonal variation in the response of mature ‘Valencia’ orange fruit to the abscission chemical CMN–pyrazole particularly with respect to the influence of young fruit, shoot, and root growth on this response (Yuan et al., 2001). The objective of the present study was to 1) determine the levels of endogenous plant hormones, especially indole-3-acetic acid (IAA), ABA, and ethylene from early November to mid June, and 2) evaluate the relationships between these endogenous hormones and the responsiveness of mature ‘Valencia’ orange fruit to the abscission chemical CMN–pyrazole.

Materials and Methods

PLANT MATERIALS. Nine uniform 10-year-old ‘Valencia’ orange trees grafted on rough lemon (Citrus × jambhiri Lush) rootstock, were selected from a previously described grove located at the Citrus Research and Education Center, Lake Alfred, Fla. (Yuan et al., 2001), and separated into three replicate groups of three trees each. Fifteen fruit having pedicels 3 to 4 cm in length were collected from each tree at 1- or 2-week intervals beginning 12 Nov. 1998 and ending 15 June 1999. Forty-five fruit from each group at each sampling time were pooled and immediately
separated into peel, pulp, seed, and abscission zone. The fruit abscission zones were removed according to the method of Kazokas and Burns (1998). Promptly after the separation of fruit, samples were frozen in liquid nitrogen, and lyophilized. All plant materials except the abscission zone were ground in a Wiley mill to pass a 40-mesh (0.635-mm) screen, and used for measurement of free IAA and ABA. An additional 15 fruit were collected on each sampling date and used for determination of fruit ethylene production. Ten fruit from each replicate were also collected, washed, and used for measurement of fruit color.

EXTRACTION, PURIFICATION, AND MEASUREMENT OF FREE IAA AND ABA. The method of Bertling and Lovatt (1996) was modified to extract and partially purify plant materials for free IAA and ABA. Briefly, 3 g of ground peel, pulp, or seed, were placed in an Erlenmeyer flask. To each Erlenmeyer flask, 80 mL of 80% methanol containing butylated hydroxytoluene (BHT) at 40 mg·L⁻¹, as an antioxidant was added, and the tissue was extracted overnight at 4 °C. The sample of abscission zone tissue was placed in a plastic centrifugation tube with 30 mL of 80% methanol containing BHT at 40 mg·L⁻¹, pulverized using a Brinkmann rotary homogenizer (Brinkmann Instruments Co., Westbury, N.Y.), transferred to an Erlenmeyer flask holding another 50 mL of 80% methanol containing BHT at 40 mg·L⁻¹, and then extracted overnight at 4 °C. One hundred microliters of 3H-IAA (∼67 Bq) and 14C-ABA (∼83 Bq) were added as internal standards to the plant samples to determine the recovery rate. The crude extract was filtered through Whatman No. 2 filter paper and the residue was reextracted twice overnight at 4 °C in 80 mL of 80% methanol containing BHT at 40 mg·L⁻¹. The filtrates were combined and evaporated to the aqueous phase in vacuo at 35 °C. The aqueous phase was stored at –20 °C overnight, thawed, and centrifuged at 15,000 g, for 20 min. The supernatant was adjusted to pH 8.0 with 5% NH₄OH and loaded onto a column system that was first preconditioned and washed with 15 mL of 1.0 M ammonium acetate (pH 8.0) and subsequently with 15 mL of 0.01 M ammonium acetate (pH 8.0). The column system consisted of an insoluble polyvinyl pyrrolidone (PVP) (10 × 1.5 cm) and a diethylaminoethyl (DEAE) Sephadex anion exchange column (10 × 1.5 cm). The column system was eluted with 0.01 M ammonium acetate (pH 8.0). A Sep-Pak C₁₈ cartridge (Waters, Milford, Mass.) that was first preconditioned with 100% methanol and subsequently with 0.1 M acetic acid was attached to the DEAE column of the column system. IAA and ABA were eluted with 15 mL of 0.01 M acetic acid and collected at the Sep-Pak C₁₈ cartridge, which was rinsed with 10 mL of distilled water before IAA and ABA were eluted with 5 mL of 50% methanol. The eluates were dried in vacuo and dissolved in 2 mL of 100% high performance liquid chromatography (HPLC) grade methanol.

The samples were further purified by HPLC according to the method of Miller et al. (1987) with some modification. In brief, a 500 µL sample containing IAA and ABA was applied to a 250 × 4.6 mm Whatman Partisil ODS-3 C₁₈ reverse phase column (5-µm particle size) at a flow rate of 1.0 mL·min⁻¹ with a 15% to 80% (v/v) gradient over a period of 30 min in a solution of 1% acetic acid, followed by an increase to 100% methanol over 5 min. Fractions corresponding to IAA and ABA were collected and dried in vacuo.

ABA fractions were diluted with 25 mM Tris buffer (pH 7.5) before quantification by an enzyme-linked immunosorbent assay (ELISA). Tris buffer was prepared by diluting 3.03 g Trizma base, 5.84 g NaCl, 0.2 g MgCl₂·6H₂O, and 0.2 g NaN₃ in 1 L of distilled water and adjusted to pH 7.5 with HCl. IAA fractions were resuspended in 250 µL of methanol, methylated with diazomethane, dried in vacuo, and redissolved in Tris buffer (pH 7.5) for assaying by ELISA. IAA and ABA were quantified by ELISA using monoclonal antibodies against IAA and ABA (Agdia Inc., Elkhart, Ind.) and the ELISA procedures were conducted as recommended by the manufacturer. The recovery rate was ≈70.2% for IAA, and 52.4% for ABA.

To determine the less-responsive period, groups of 20 uniform mature fruit were selected, marked, and sprayed with CMN–Pyrazole at 150 mg·L⁻¹ on each of four replicate trees on each date.
at 7 to 10 d intervals from 9 Mar. 1999 to 2 June 1999 as reported in detail previously (Yuan et al., 2001). A total of 11 spray treatments were applied during the 3-month observation period. Fruit detachment force (FDF) was measured 7 d after each spray application using a digital force gauge (Force Five, Wagner Instruments, Greenwich, Conn.) (Hartmond et al., 2000a). The correlation between the endogenous hormone status (IAA, ABA, and their ratio) of nontreated mature fruit and the response in FDF of mature ‘Valencia’ orange fruit to the abscission chemical CMN–pyrazole were analyzed during 9 Mar. to 2 June 1999.

**Ethylene Measurement.** Ethylene concentration of mature ‘Valencia’ fruit was measured according to Hartmond et al. (2000b). Briefly, internal air was evacuated by vacuum from fruit submerged in degassed water and collected. Ethylene concentrations were measured with a gas chromatograph (Hewlett-Packard, Avondale, Pa.) equipped with an alumina column and flame ionization detector.

**Fruit Color Measurement.** On each sampling date, the peel color (chroma and hue angle) of 30 washed fruit was measured at three positions of each fruit around the equator using a chroma meter (CR200; Minolta Co., Asaka, Japan) measuring in CIE 1976 (L*, a*, b*) (McGuire, 1992) [CIE = Commission Internationale de l’Eclairage (International Commission on Illumination)]. Chroma (C*), calculated as $(a^*^2 + b^*^2)^{1/2}$, is an index of color saturation or intensity (degree of departure from gray toward pure chromatic color). Hue angle (h°) (0° = red-purple, 90° = yellow, 180° = bluish green, and 270° = blue) is calculated from the arctangent of a*/b*.

**Results**

Endogenous IAA concentrations in the abscission zone of ‘Valencia’ orange fruit were low, ranging from ≈20 to 40 pmol·g⁻¹ dry weight (DW), from 12 Nov. 1998 to 16 Apr. 1999 (Fig. 1A). They increased dramatically in late April, reached a peak level of ≈70 pmol·g⁻¹ DW on 14 May, and decreased thereafter. Overall, IAA concentration in the peel of fruit was markedly higher than that in the pulp, seed, and abscission zone over the more than 7 month observation period (Fig. 1A and B). IAA concentration in the peel was high (≈500 pmol·g⁻¹ DW) from 12 Nov. 1998 to 13 Jan. 1999, and decreased thereafter to a low level of ≈200 pmol·g⁻¹ DW in early April. After 16 Apr. 1999, the IAA concentration increased and remained at a higher level (≈400 pmol·g⁻¹ DW) throughout the remainder of the sampling period. The period of less responsiveness of mature ‘Valencia’ orange fruit to CMN–pyrazole started late April and ended in late May (Yuan et al., 2001).

ABA concentration in the abscission zone of ‘Valencia’ orange fruit was low (≈200 pmol·g⁻¹ DW) in Nov. 1998, increased thereafter, and remained at a relatively high level (≈800 to 1200 pmol·g⁻¹ DW) from late January to mid-April 1999 (Fig. 2A). ABA concentration decreased rapidly to ≈420 pmol·g⁻¹ DW by 23 Apr. 1999, and remained at a low level for 4 weeks followed by another abrupt increase. ABA concentration in the pulp was low over the entire observation period (Fig. 2B). The ABA concentration in the peel was low (≈400 pmol·g⁻¹ DW) in Nov. 1998, and increased dramatically thereafter to a peak level of 1600 pmol·g⁻¹ DW in early January 1999 (Fig. 2B), followed by a steady decrease. After late March, ABA concentration in the peel was generally lower (≈400 pmol·g⁻¹ DW or less). The ABA concentration in the seed was low from late March to early May, and increased rapidly thereafter (Fig. 2B).

The ratio of IAA to ABA in the abscission zone of ‘Valencia’ orange fruit was high in November 1998, and then decreased gradually until late April 1999 (Fig. 3A). It increased ≈3-fold after late April, and remained at a high level during the less responsive period. The ratio decreased again after late May when the less responsive period was over. The ratio of IAA to ABA in peel of mature ‘Valencia’ orange fruit was much higher than that in the abscission zone and showed a trend similar to that in the abscission zone, but less pronounced (Fig. 3B).

FDF of CMN–pyrazole-treated fruit was positively correlated with the ratio of endogenous IAA to ABA or endogenous IAA, but negatively correlated with endogenous ABA in the abscission zone (Fig. 4A, B, and C). There was no significant correlation between the FDF of CMN–pyrazole-treated fruit and endogenous IAA or ABA in the peel (Fig. 4E and F); however, there was a quadratic relationship between the ratio of endogenous IAA to ABA in peel and the FDF of CMN–pyrazole-treated fruit (Fig. 4D).

Overall, the ethylene concentration of nontreated ‘Valencia’ orange fruit was low during the observation period (Fig. 5). Fruit had slightly more ethylene during the period from late December 1998 to mid-February 1999 than at any other time of the observation period.

C* decreased quickly after early May, reflecting that fruit
color became less intense (Fig. 6A). Hue were low in March and April, and increased rapidly after mid-May, indicating fruit were yellow orange until mid-May when regreening occurred (Fig. 6B).

**Discussion**

Fruit abscission, irrespective of maturity (young or mature), occurs at the abscission zone of the fruit. It is generally accepted that the balance between plant growth promoters and inhibitors are involved in fruit abscission (Addicott, 1982; Brown, 1997; Garcia-Papi and Garcia-Martinez, 1984; Goren, 1993; Guinn and Brummett, 1988). In oranges, it is well documented that abscission chemicals effectively reduce FDF and promote mature fruit abscission by stimulating ethylene production (Hartmond et al., 2000b; Holm and Wilson, 1976, 1977; Wheaton et al., 1977). This is followed by initiation of expression of genes of cellulase and polygalacturonase (Kazokas and Burns, 1998), de novo synthesis of hydrolytic enzymes in the abscission zone, degradation of the cell wall, and finally separation (Goren, 1993; Kazokas and Burns, 1998). However, beginning in late April and lasting for ≈4 weeks, there is a period of less responsiveness of mature ‘Valencia’ orange fruit to abscission chemicals (Cooper and Henry, 1972; Hartmond et al., 2000a; Wheaton et al., 1977; Yuan et al., 2001). In our study, the abscission zone had relatively high concentrations of endogenous IAA and low concentrations of endogenous ABA during the less responsive period. Detachment force of fruit treated with the abscission chemical, CMN–pyrazole, was positively associated with IAA, but negatively with ABA in the abscission zone. These results indicate that response of mature ‘Valencia’ orange to the abscission chemical CMN–pyrazole is affected by the balance between IAA and ABA. Similarly, reduction in the endogenous IAA level and the increase of the endogenous ABA level in the abscission zone have been suggested to be responsible for water stress-induced young fruit abscission in cotton (*Gossypium hirsutum* L.) (Guinn and Brummett, 1988) and high temperature-induced abscission of pepper (*Capsicum annuum* L.) flowers and fruit (Huberman et al., 1997). It has been suggested that endogenous IAA and ABA in the abscission zone are antagonistic in controlling responsiveness of ‘Valencia’ orange fruit to abscission chemicals. Poor response of ‘Valencia’ orange fruit to CHI in October and very early December reported by Cooper and Henry (1972) might also be due to the high ratio of IAA to ABA in the abscission zone that we measured during that period (Fig. 3A). Our recent unpublished results showed that the response of mature ‘Valencia’ orange fruit to CMN–pyrazole was poor in October, November, and early December.

Fruit abscission usually has a closer relationship with the endogenous hormones in the abscission zone than in the fruit themselves. Heat stress induced abscission of reproductive or-
introduction through the stem, spray application of ABA was less effective in inducing fruit abscission, since less ABA was translocated to the abscission zone. Abscission chemicals were also more efficient in promoting fruit abscission when they were applied directly to the abscission zone than to the fruit (Hartmond et al., 2000b). The ABA peak in the peel but not in the abscission zone measured in January was possibly the result of cold weather (5 to 10 °C). The source of the high IAA concentration in the abscission zone and the peel during the less responsive period has
gans of bean (Ofir et al., 1993) or pepper (Huberman et al., 1997) was not closely related to changes of endogenous IAA levels in the reproductive organs, but closely related to changes in the abscission zone. In the present studies, response of mature ‘Valencia’ orange fruit to CMN–pyrazole also had a less pronounced relationship with endogenous concentrations of IAA and ABA in the peel, which are the major sources of these hormones in Citrus (Monselise, 1977), than in the abscission zone. Similarly, Rasmussen (1974) reported that compared with the introduction through the stem, spray application of ABA was less effective in inducing fruit abscission, since less ABA was translocated to the abscission zone. Abscission chemicals were also more efficient in promoting fruit abscission when they were applied directly to the abscission zone than to the fruit (Hartmond et al., 2000b). The ABA peak in the peel but not in the abscission zone measured in January was possibly the result of cold weather (5 to 10 °C). The source of the high IAA concentration in the abscission zone and the peel during the less responsive period has

Fig. 4. Correlations between the detachment force of mature fruit treated with CMN–pyrazole at 150 mg·L⁻¹, and endogenous levels of IAA and ABA or their ratio in the (A, B, and C) abscission zone or (D, E, and F) peel of mature ‘Valencia’ orange fruit. NS, *, ** Nonsignificant or significant at \( P < 0.05 \) or \( 0.01 \), respectively.
not been established. Further experiments to determine effects of removal of young fruit alone or in combination with removal of spring vegetative shoots on changes of endogenous hormones in the abscission zone, peel, pulp, and seed of mature fruit during the less responsive period are being conducted to elucidate the sources of endogenous hormones.

Fruit ethylene production was low during the observation period except during the cool winter months (Fig. 5). Our results agreed with previous reports that *Citrus* fruit do not produce increased ethylene at maturation (Brown, 1997; Goren, 1993). The natural fruit ethylene concentration had no close relation with the less responsive period.

Results herein showed that fruit regreening occurred in mid- or late-May at the end of the less responsive period, which is consistent with previous reports that regreening of fruit rind and the less responsive period were not associated (Wheaton et al., 1977). It appears that endogenous IAA, ABA, or the ratio of endogenous IAA to ABA in the peel had no influence on fruit rind color.

In conclusion, our results suggest that the balance between IAA and ABA in the fruit abscission zone may be an important factor in determining sensitivity of mature ‘Valencia’ orange fruit to abscission chemicals, thereby controlling the response of mature ‘Valencia’ orange fruit to abscission chemicals. Endogenous IAA, ABA, or the ratio of endogenous IAA to ABA in the peel seem to be not associated with the regreening of fruit rind.
