Recent theoretical work suggests that violation of the Equivalence Principle might be revealed in a measurement of the fractional differential acceleration \( \eta \) between two test bodies—from different composition, falling in the gravitational field of a source mass— if the measurement is made to the level of \( \eta \approx 10^{-13} \) or better. This being within the reach of ground based experiments, gives them a new impetus. However, while slowly rotating torsion balances in ground laboratories are close to reaching this level, only an experiment performed in low orbit around the Earth is likely to provide a much better accuracy.

We report on the progress made with the “Galileo Galilei on the Ground” (GGG) experiment, which aims to compete with torsion balances using an instrument design also capable of being converted into a much higher sensitivity space test.

In the present and following paper (Part I and Part II), we demonstrate that the dynamical response of the GGG differential accelerometer set into supercritical rotation—in particular its normal modes (Part I) and rejection of common mode effects (Part II)—can be predicted by means of a simple but effective model that embodies all the relevant physics. Analytical solutions are obtained under special limits, which provide the theoretical understanding. A simulation environment is set up, obtaining quantitative agreement with the available experimental data on the frequencies of the normal modes, and on the whirling behavior. This is a needed and reliable tool for controlling and separating perturbative effects from the expected signal, as well as for planning the optimization of the apparatus.

I. INTRODUCTION

Experimental tests of the Equivalence Principle (EP) are of seminal relevance as probes of General Relativity. The Equivalence Principle is tested by observing its consequence, namely the Universality of Free Fall, whereby in a gravitational field all bodies fall with the same acceleration regardless of their mass and composition. They therefore require two test masses of different composition, falling in the field of another ‘source’ mass, and a read-out system to detect their motions relative to one another. An EP violation would result in a differential displacement of the masses in the direction of the source mass, which cannot be explained on the basis of known, classical phenomena (e.g. tidal effects).

The landmark experiment by Éötvös and collaborators [11] has established that a torsion balance is most well suited for ground tests of the EP, thanks to its inherently differential nature. With the test masses suspended on a torsion balance they improved previous pendulum experiments by almost 4 orders of magnitude, showing no violation for \( \eta \) larger than a few \( 10^{-9} \) [11]. Several decades later, by exploiting the 24-hr modulation of the signal in the gravitational field of the Sun, torsion balance tests have improved to \( 10^{-11} \) [2] and then to \( 10^{-12} \) [3]. More recently, systematic and very careful tests carried out by Adelberger and co-workers using rotating torsion balances have provided even more firm evidence that no violation occurs to the level of \( 10^{-12} \) [4, 5].

The relevant theoretical question for Equivalence Principle tests is: at which accuracy level a violation, if any, is to be expected? In an earlier work by Damour and Polyakov, based on string theory and the existence of the dilaton [6], \( \eta \) values at which a violation might be observed have been determined to be in the range \( 10^{-18} < \eta < 10^{-13} \). Fischbach and coworkers [7] have derived a non-perturbative rigorous result, according to which a violation must occur at the level of \( \eta \approx 10^{-17} \), due to the coupling between gravity and processes of \( \nu-\bar{\nu} \) exchange which should differently affect masses with different nuclei. More recent work [8] suggests, in a new theoretical framework for the dilaton, that a violation might occur already at the level of \( \eta \approx 10^{-12} - 10^{-13} \), depending on the composition of the masses.

While an \( \eta \approx 10^{-13} \), and perhaps smaller, should be accessible with rotating torsion balance experiments on the ground, a sensitivity as high as \( \eta \approx 10^{-17} \) could be achieved only by an experiment flying in low Earth orbit, where the driving acceleration is up to three orders of magnitude larger. Specific instruments have been designed to carry out such an experiment in space: STEP, Microscope and “Galileo Galilei” (GG) [9-12]. They share two features: that the test masses are concentric cylinders, and that rotation of the spacecraft provides signal modulation at frequencies higher than the orbital
GGG is peculiar in that it spins around the symmetry axis and is sensitive to relative displacements in the plane perpendicular to it: cylindrical symmetry of the whole system and rotation around the symmetry axis allow passive attitude stabilization of the spacecraft with no need of a motor after initial spin up to the nominal frequency (typically 2 Hz). The planar (instead of linear) sensitivity of the instrument is also a crucial feature for allowing us to rotate at supercritical speeds, i.e. faster than the natural frequencies of the system. Faster rotation means modulation of the signal at higher frequency and therefore a reduced $1/f$ noise (for $1/f$ noise see e.g. the website maintained by W. Li [13]). GGG differs from the other proposed space experiments also in that the test masses are suspended mechanically. We find that in absence of weight, as it is the case in space, mechanical suspensions too can provide extremely weak coupling, with the additional advantage to electrically ground the test masses.

The GG design naturally allows us to build and test a full scale 1-g version of the apparatus: by suspending the instrument on a rotating platform through its spin/symmetry axis, the sensitive plane lies in the horizontal plane of the laboratory where a component of an EP violation signal might be detected, similarly to a torsion balance experiment. “Galileo Galilei on the Ground” (GGG) [14, 15] is primarily a prototype for testing the main novel features of the experiment proposed for flight. It is also an EP experiment in its own right aiming to compete with torsion balance tests [2] [2]. In this effort, motor noise, low frequency terrain tilts [10] and tidal perturbations [17] are the main issues to be addressed.

A full knowledge of the dynamical response of the GGG rotor is needed, especially in view of its condition of supercritical rotation, and of its common mode rejection behavior. The theoretical understanding of the dynamical properties of the rotor, together with the construction of a full simulation facility, would allow us to predict and interpret the collected experimental data; they also provide a virtual environment for planning the experiment and optimizing its performance.

With these motivations in mind, we demonstrate that a simple but very effective mathematical model can be set up to quantitatively describe the dynamical properties of the GGG rotor. In this paper (Part I), we determine the normal modes in all regimes, from subcritical to supercritical rotation, and address the issue of self-centering in supercritical rotation. In the following paper (Part II), we provide the dependence of the common mode rejection ratio on various system parameters which govern the design of the instrument.

The differential equations in the model are solved by means of a user-friendly simulation program and the numerical solutions are tested against the data available from the experiment. The physical content of the model is also discussed by means of approximate analytical solutions, which provide useful physical insight.

This paper is organized as follows: Sec. III describes the main features of the experimental apparatus; Sec. IV presents the dynamical model of the system, referring to specific appendices for details. Sec. IV reports on the numerical method that we have implemented and Sec. V gives the results obtained on the determination of the normal modes of the system, showing an excellent agreement between theoretical predictions and experimental data. The details of the calculations are contained in two appendices, while the third one is specifically devoted to the important concept of self-centering. Concluding remarks are discussed in Sec. VI.

II. THE GGG ROTOR: OVERVIEW OF THE EXPERIMENT

GGG is a rotating differential accelerometer operated in a vacuum chamber (see Fig. 1). It is made of two concentric hollow test cylinders, 10 kg each, weakly coupled by means of a vertical arm—a tube located along the axis of the cylinders— to form a vertical beam balance (from now on we shall always omit the term “hollow” when referring to the test cylinders). The coupling arm is suspended at its midpoint from a rotating vertical shaft in the shape of a tube enclosing it (see Fig. 1 and Fig. 2, right hand side). A total of three suspensions are needed (drawn in red in Fig. 1): a central one (see Fig. 2, left hand side) to suspend the coupling arm from the rotating shaft, and one for each test cylinder to suspend each of them from the top and bottom end of the vertical coupling arm.

The suspensions are cardanic laminar suspensions manufactured in CuBe which are stiff in the axial direction $\hat{Z}$, against local gravity, and soft in the plane $\hat{X} - \hat{Y}$ orthogonal to the axis so that the geometry is naturally two-dimensional, the horizontal plane being sensitive to differential accelerations acting between the test cylinders. In normal operation mode, modulation of such a signal is provided by setting the whole system in rotation around the vertical axis in supercritical regime, namely at frequencies $\nu_s$ larger than the natural differential frequencies of the rotor, typically $\nu_s > 1.5$ Hz. The differential character of the instrument is strengthened by two differential read-out systems made of four capacitance plates (indicated as $IP$, internal plates, in Fig. 1) located in between the test cylinders and which are part of two capacitance bridges in two orthogonal directions of the sensitive plane.

A. Description of the mechanical structure of the apparatus

The GGG apparatus is schematically presented in Fig. 1, where a section through the spin-symmetry axis $\hat{Z}$ is shown inside the vacuum chamber $C$. At the top-center of the frame is the motor $M$ whose shaft is connected to
FIG. 1: Section through the spin axis $\hat{Z}$ of the differential accelerometer inside the vacuum chamber. $C$: vacuum chamber; $M$: motor; $OD$: optical device (see Sec. II B); $x$: ball bearings; $ST$: suspension tube; $A$: coupling (balance) arm, located inside the suspension tube, with its 3 laminar cardanic suspensions (in red); $G$: center of mass of the two cylinder’s system (in blue the outer cylinder, in green the inner one, 10 kg each). $IP$ are the internal capacitance plates of the differential motion detector (Sec. II B), $OP$ are the outer ones for whirl control (Sec. II C 2). $PC$ is the contactless inductive power coupler providing power to the electronics inside the rotor. The relevant distances $L_i$, and $L_o$ of the centers of mass of the inner and outer bodies from their suspension points are also sketched, along with the arm length $2L_o + \Delta L$. $T$ and $P$, at the top of the rotor, are the tiltmeter and 3 PZTs (at 120° from one another –only one shown) for automated control of low frequency terrain tilts. The drawing is to scale and the inner diameter of the vacuum chamber is 1 m.

The suspension tube of the rotor $ST$ (drawn in yellow) by means of an appropriate motor-rotor joint and turns in the vertical direction inside ball bearings, indicated by $x$ symbols in the figure. From the suspension tube $ST$ rotation is then transmitted to a tube located inside it which constitutes the vertical beam of the balance (also referred to as the coupling arm, Fig. 2 right hand side), the connection between the two being provided at the midpoint of the arm by the central laminar cardanic suspension (see Fig. 2 left hand side).

The coupling arm in its turn transmits rotation to both the test cylinders, since they are suspended (by means of two laminar cardanic suspensions similar to the central one) from its two ends. More precisely, the inner test cylinder (shown in green) is suspended from the bottom of the coupling arm at a distance $L_i$ from the cylinder’s center-of-mass, while the outer one (shown in blue), is suspended from the top of the coupling arm, at a distance $L_o$ from the cylinder’s center-of-mass. In Fig. 1 the three suspensions are drawn in red. It is apparent that the central suspension carries the whole weight of the rotor, mostly the weight of the two test cylinders (10 kg each) plus the small weight of the coupling arm. It is worth noting that the metallic suspensions provide passive electrostatic discharging of the test masses.

FIG. 2: Left hand side: the central laminar cardanic suspension of the GGG rotor, located at the midpoint to the coupling arm in order to suspend it from the suspension tube (shaft). Right hand side: the coupling arm inside the suspension tube (shaft) as seen from the top. Two cardanic laminar suspensions are located at its top and bottom ends. They suspend the test cylinders (not shown here) through two metal rings. The dimensions of the rings depend on the dimensions of the concentric cylinders, which have equal mass (10 kg) and therefore different size. Top and bottom ring refer to outer and inner test cylinder respectively.

In this way, the symmetry of the whole apparatus is cylindrical, its axis being both the vertical beam of the balance and the axis of rotation, the balance is sensitive in the horizontal plane and the test masses are concentric.

B. The differential motion detector system

The Differential Motion Detector (DMD) reflects the cylindrical symmetry of the system and is composed of the following three parts.

(1) Two capacitance plates $IP$ working as DMD($x$) sensors (drawn as vertical lines in between the cylinders
in Fig. 1, are located halfway in between the test cylinders in correspondence to the $X$ direction with a clear gap of 5 mm on either side and are connected to the suspension tube by means of an insulating frame. A similar pair of capacitances forming a DMD(y) is placed in the $Y$ direction. A voltage signal is applied to each capacitance bridge in order to shift the signal of interest to a high-frequency band with reduced $1/f$ noise (with phase locked detection). The filtered signal is digitized by an ADC before transmission to the non-rotating (laboratory) frame. Calibration and balancing of the capacitance bridge are performed by means of procedures outlined in [14]. The best sensitivity achieved in bench tests corresponds to mechanical displacements of 5 pm in 1 s of integration time [11, 14]. Presently, the sensitivity of the read-out system during normal operation is $\simeq 10^{-9}$ m.

(2) An optical device $OD$ located below the motor and above the ball bearings, utilizing a disk with 32-holes and an infra-red emitter-detector pair, provides a reference signal for the angular position of the rotor. The reference signal is combined with the $X$ and $Y$ channel data from the DMD and encoded into RS232 format for transmission to a computer. Then a second emitter-detector pair located at the very bottom of the rotor (using a hole along the axis of the power coupler $PC$, see Fig. 1) transmits the digital signal from the rotor to the non-rotating frame from where it is taken out of the vacuum chamber through electrical feed-throughs.

(3) An annular disk, in two semicircular parts, is mounted around the upper half of the suspension tube and contains the two capacitance-bridge circuits and their preamplifiers (see Fig. 1). The necessary electronics to demodulate the signal and convert it from analogue to digital form, as well as the drivers for the optical emitter are also located here.

C. Principle of operation

For detecting an EP violation signal the instrument relies on its sensitivity to relative displacement of the two test masses, which in the final design will be made of different materials. An acceleration in the horizontal plane of the laboratory acting differently between the test cylinders gives rise to a relative displacement of the two in the direction of the acceleration. This displacement unbalances the capacitance bridges and gives rise to an electric voltage proportional to it.

A modulation of the displacement, as seen by the capacitance plates, is achieved by setting the whole system in rotation around the vertical axis of symmetry passing through the shaft, as shown in Fig. 1. Note that the signal modulation obtained in this way does not affect the centers of mass of the test cylinders, hence it does not affect their relative displacement, which is the physical quantity measured in the experiment. As a result, this type of modulation reduces the noise but not the signal.

In point of fact, this signal modulation could be achieved by keeping the test cylinders stationary and rotating only the capacitance plates (located in between the two, indicated as $IP$ in Fig. 1) which form the differential motion detector system described above. However, by rotating the test cylinders together with the capacitors, any irregularity in their mass distribution averages out; moreover, the supercritical regime can be exploited to reduce rotation noise for all parts of the apparatus (see Sec. II C 2 and Appendix C). As for the experiment in space, rotation of the whole spacecraft has two more very important advantages. In the first place, it eliminates the need for motor and ball bearings altogether, which are a considerable source of noise in the ground experiment. Secondly, by rotating around the axis of maximum moment of inertia, the spacecraft is passively stabilized, thus reducing its weight, cost and complexity, as well as disturbances on the EP experiment.

An EP violation signal in the gravitational field of either the Earth or the Sun would have a component in the horizontal plane of the laboratory which could be detected by the instrument. Since the test bodies are rotors suspended on the Earth, and the Earth rotates around its axis, this diurnal rotation gives rise to large gyroscopic effects on the test bodies resulting in a non zero differential acceleration which would mask an EP violation signal in the field of the Earth itself. Measurements of such gyroscopic effects have been reported in [14] (Sec. 5, Fig. 12). The instrument—in this ground based version—is therefore used for two purposes: i) to establish its sensitivity as a prototype of the flight instrument, namely for an expected signal at the orbital frequency of the satellite ($\simeq 1.75 \cdot 10^{-4}$ Hz, i.e. about 1 and half hour period, at an Earth orbiting altitude of $\simeq 520$ km); ii) to look for an EP violation in the gravitational field of the Sun, in which case the signature of the signal (see [12], Sec. 2) would have a dominant Fourier component of 24-hr period due to the diurnal rotation of the Earth.

1. Differential character and common mode rejection

The differential character of the whole instrument, namely its capability to reject accelerations which are common to both test masses, is in principle ensured by the geometry and mounting of the test masses. It is further augmented by the differential nature of the DMD system.

(i) The sensitivity of the instrument to differential accelerations of the test masses depends on the softness of the laminar suspensions and on the uniform distribution of mass around the spin axis. Soft suspensions and a good balancing of the rotor provide long natural periods for differential oscillations of the test masses relative to each other, giving rise to larger relative displacements between the two, and in turn to stronger output voltage signals.

Tuning of the natural differential period $T_D$ of the test
cylinders is made possible by changing a moment-arm in the beam balance. This is accomplished by moving a small solid ring mounted at the lower end of the balance (coupling) arm. Moving this ring vertically along the arm, in the \( \hat{Z} \) direction, displaces the center-of-mass of the balance arm from its suspension point by a quantity \( \Delta L \). If \( \Delta L = 0 \) the center-of-mass of the balance arm is coincident with its suspension point. \( \Delta L \) can be adjusted to be either slightly positive or negative, resulting in a longer or shorter \( T_D \). However, there’s a maximum positive value that \( \Delta L \) can assume before the system becomes unstable (see Eq. (11) below).

Asymmetric distribution of mass of the rotor in the horizontal plane, resulting in a non-zero inclination of the coupling arm in the rotating reference frame, may also be corrected by two small masses mounted inside the coupling arm itself, one of which is movable in the X direction and the other in the Y.

The tilt of the spin axis with respect to the non-rotating laboratory frame is controlled by three micrometer screws which support the plate on which the rotor shaft is mounted. In addition the tilt can be finely adjusted using piezoelectric actuators (P) attached to the tips of the micrometer screws (see Fig. 1).

(ii) As to the DMD system, a non-zero off-centering of the capacitor plates \( IP \) located in between the test cylinders – measured by the ratio \( (a-b)/a \) where \( a \) \( b \) is the nominal gap between the inner (outer) mass and any one of the capacitance plates – would make a common mode displacement \( \Delta x_C \) of the test masses to produce a differential output signal in addition to that produced by a real differential displacement \( \Delta x_D \). The larger this off-centering, the larger the fraction of common mode displacement which is turned into a ‘fake’ differential signal, i.e. which contributes to the total imbalance \( \Delta C \) of the capacitance bridge [11] (GG Phase A Report, Sec. 2.1.3) from the original capacitance value \( C_0 \):

\[
\frac{\Delta C}{2C_0} \approx \frac{a-b}{a^2} \Delta x_C - \frac{1}{a} \Delta x_D.
\]

2. Signal modulation and whirl motions

Signal modulation in testing the equivalence principle has been first proposed in [2] in order to improve the Eötvös experiments. By referring to the Sun rather than the Earth as the source mass of the gravitational field, the diurnal rotation of the Earth itself on which the test masses are suspended provides a 24-hr modulation with no need to rotate the experimental apparatus, an operation which gives rise to relevant disturbances in such small force experiments. However, higher modulation frequencies are desirable in order to reduce \( 1/f \) noise, and in fact excellent results have been obtained by [4, 5] with torsion balances placed on a turntable rotating faster than the Earth. In GGG we try to spin the test masses much faster, at frequencies (typically a few Hz) higher than the natural frequencies \( \nu_n \) of the system, a condition known as supercritical rotation.

The GGG apparatus has 3 natural frequencies. The differential frequency \( \nu_D \), of the oscillations of the test bodies relative to one another, and two common mode frequencies, \( \nu_{C1} \) and \( \nu_{C2} \), of both test masses together. In the GGG setting reported here their values are: \( \nu_D = 0.09 \) Hz, \( \nu_{C1} = 0.91 \) Hz, \( \nu_{C2} = 1.26 \) Hz.

It is well known [14, 21, 22] that in supercritical rotation the masses are able to self-center and greatly reduce the original offsets of their centers of mass with respect to their own rotation axes. Any initial offset, which inevitably results from construction and mounting errors, is in fact reduced by a factor \( (\nu_D/\nu_n)^2 \). Such self-centering is a very essential requirement when using fast rotating macroscopic test bodies for the purpose of detecting the effects of extremely small forces between them.

It is also well known that in supercritical rotation, dissipation in the system gives rise to destabilizing whirl motions at frequencies \( \nu_w \) equal (or close) to the natural frequencies of the system, whose amplitude increases with time at a rate \( 1/\tau_w = \pi \nu_w/Q(\nu_w) \) scaling as the whirl frequency \( \nu_w \) and the inverse of the quality factor \( Q \) at the spin frequency \( \nu_s \) [21, 22, 23].

Whirls can be stabilized by passive and active methods. Passive stabilization is typically used in engineering applications of supercritical rotors, but it produces too large disturbances for our purposes. We have used a passive damper in the past only to stabilize the rotor during resonance crossing (see [14], Sec. 3). With the current improved apparatus, damping at resonance crossing is no longer needed. A much finer whirl stabilization can be performed actively by means of 8 small capacitance sensors/actuators (indicated as \( OP \), outer plates, in Fig. 1) placed close to the outside surface of the outer test cylinder, 4 of them used as sensors and 4 as actuators in two orthogonal directions of the horizontal plane [15]. In the GGG experiment performed at supercritical speed the relevant \( Q \) value is determined by losses due to deformations of the laminar suspensions at the spin frequency. Experimental measurements of \( Q \) are reported in [14] and, more recently, in [18].

III. THE MODEL

Having described the real instrument, we are now in a position to outline the minimal model used to describe its dynamical behavior. Fig. 8 displays a schematic representation of the model in the reference frame \{X’Y’Z’\} rotating with the shaft at an angular velocity \( \omega_\nu = 2\pi \nu_s \) around the Z’ axis (\( \hat{\omega}_s = \omega_s Z' \)). The relevant parts of the instrument depicted in Fig. 1 are sketched in Fig. 8 with the same colors. The coupling arm, with mass \( m_a \) (drawn in cyan as in Fig. 1), and length \( 2L_a + \Delta L \) is suspended at its midpoint \( MP \) from the rotating shaft and suspension tube \( ST \) (yellow) by means of the central laminar suspension \( LS \) (red) with elastic constant
The vector \( \vec{\varepsilon} \) is the offset of the arm center-of-mass from the axis, which is unavoidable because of construction and mounting errors. Variations of \( \Delta L \), as we have already discussed, produce a change of the mass distribution, hence of the natural differential period of the test masses, \( T_D \). Here, and with no loss of generality, \( \vec{\varepsilon} \) is placed along the \( X' \) axis.

The outer test cylinder, of mass \( m_o \) (blue), is suspended from the top of the coupling arm by means of the laminar suspension with elastic constant \( K_o \) and its center of mass is at a distance \( L_o \) from the suspension. In a similar manner, the inner test mass \( m_i \) (green) is suspended from the bottom of the arm, \( K_i \) and \( L_i \) being the corresponding parameters. From now on, the label \( \lambda = i, o, a \) will be used to refer to the parameters of the inner mass, outer mass, and coupling-arm respectively. The three bodies have moments of inertia \( I_{\lambda} = m_{\lambda} \frac{3}{2} R_{\lambda E}^2 + \frac{1}{12} R_{\lambda H}^2 \) along their principal axes \( (\xi, \eta, \zeta) \), \( R_{\lambda I}, R_{\lambda E} \) being the internal and external radii of the cylinder \( \lambda \), and \( R_{\lambda H} \) its height.

By defining the unit vector \( \hat{L}_a \) of the coupling arm as pointing from its midpoint towards the bottom suspension, and the unit vectors \( \hat{L}_o \) and \( \hat{L}_i \) of the test cylinders each pointing from the suspension to the center of mass of the body (see Fig. 3), the corresponding position vectors in the rotating reference frame \( \{X'Y'Z'\} \) of Fig. 3 are

\[
\begin{align*}
\hat{R}_o & = \vec{\varepsilon} - 0.5 \Delta L \hat{L}_a \\
\hat{R}_o & = \vec{\varepsilon} - (L_o + \Delta L) \hat{L}_a + L_o \hat{L}_o \\
\hat{R}_i & = \vec{\varepsilon} + L_o \hat{L}_o + L_i \hat{L}_i .
\end{align*}
\]

**A. The Lagrangian**

The Lagrangian \( \mathcal{L} \) in the rotating reference frame \( \{X'Y'Z'\} \) can be written as

\[
\mathcal{L} = T - U ,
\]

where the kinetic term can be very generally written as

\[
T = \frac{1}{2} \sum_{\lambda = a, o, i} \int \dot{\vec{\varepsilon}}_\lambda^2 dm_\lambda 
\]

after defining the velocity \( \dot{\vec{\varepsilon}}_\lambda \) of the mass element \( dm_\lambda \) in body \( \lambda \) with volume \( \tau_\lambda \). Then, \( U \) includes the potential energies associated with gravity and with the elastic forces, namely

\[
U = U_g + U_{el} 
\]

where

\[
\begin{align*}
U_g & = \sum_{\lambda = a, o, i} -m_\lambda \vec{g} \cdot \hat{R}_\lambda \quad \text{with} \quad \vec{g} \equiv -g \hat{Z}' \\
U_{el} & = \sum_{\lambda = a, o, i} \frac{1}{2} K_\lambda \dot{\vec{r}}_\lambda \times \hat{R}_\lambda \, | \hat{R}_\lambda |^2 \\
& \quad + \frac{1}{2} L_o^2 \left( K_{Y'} |\hat{R}_o \times \hat{X}'|^2 + K_{Y'} |\hat{R}_o \times \hat{Y}'|^2 \right) \, .
\end{align*}
\]

For the expression of \( U_{el} \) we refer to the small figure at the bottom right of Fig. 3 sketching the laminar suspension and its orientation.

We proceed along the main steps to derive the operational expression for \( \mathcal{L} \). The bodies are rotating around their own axis with angular velocity \( \omega_s \) in a reference frame which is rotating as well, as sketched in Fig. 3 right hand side. Thus, we define as \( \vec{\Omega}_\lambda \) the angular-velocity vector of the element \( dm_\lambda \) in the \( \{X'Y'Z'\} \) frame and \( \vec{\omega}_s \equiv \omega_s \hat{Z}' \), so that

\[
\vec{\varepsilon}_\lambda = \vec{V}_\lambda + \vec{\Omega}_\lambda \times \vec{r}_\lambda = \vec{V}_\lambda + \vec{r}_\lambda \times (\hat{R}_\lambda + \hat{\rho}_\lambda) ,
\]

where \( \vec{V}_\lambda \) is the velocity of the center-of-mass of body \( \lambda \) and \( \vec{r}_\lambda \) is the vector pointing to the element \( dm_\lambda \), composed by \( \hat{R}_\lambda \) and \( \hat{\rho}_\lambda \) as drawn in Fig. 3. By inserting Eqs. 9 into Eq. 10, we can write \( T \) as

\[
T = T_{kin} + T_{Cor} + U_{Cor} + U_c ,
\]
where the only non-zero terms are (see Appendix A for details)

\[
T_{\text{kin}} = \frac{1}{2} \sum_{\lambda} \left( m_{\lambda} V_{\lambda}^2 + \sum_{\alpha=\xi,\eta,\zeta} I_{\lambda \alpha} \omega_{\alpha}^2 \right) \tag{11}
\]

\[
T_{\text{Cor}} + U_{\text{Cor}} = \sum_{\lambda} m_{\lambda} \vec{V}_{\lambda} \cdot \left( \vec{\omega} \times \vec{R}_{\lambda} \right) \tag{12}
\]

\[
+ \sum_{\lambda} \int_{\tau_{\lambda}} \left( \vec{\Omega} \times \vec{\rho}_{\lambda} \right) \cdot \left( \vec{\omega} \times \vec{\rho}_{\lambda} \right) \, dm \tag{13}
\]

\[
U_c = \frac{1}{2} \sum_{\lambda} \int_{\tau_{\lambda}} \left[ \vec{\omega} \times \left( \vec{R}_{\lambda} + \vec{\rho}_{\lambda} \right) \right]^2 \, dm \tag{14}
\]

In Eqs. (12)–(13) the terms coming from Coriolis forces have been split into the \( U_{\text{Cor}} \) potential energy, which contains only the position vectors, and \( T_{\text{Cor}} \) which contains also the velocities. The centrifugal part \( U_c \) has been indicated as a potential energy. To proceed further, we now have to specify the choice of the generalized coordinates.

**B. Choice of the generalized coordinates**

The GGG rotor model shown in Fig. 3 is composed of \( n_b = 3 \) coupled bodies, for a total of 18 degrees of freedom. However, the central suspension prevents them from performing translational motions, thereby reducing the degrees of freedom to 9. In addition, the motor forces the three bodies to rotate at a constant angular velocity, so that the number of degrees of freedom for the model is \( n = 6 \).

We have chosen as generalized coordinates for each body the two angles \( \theta_\lambda \) and \( \phi_\lambda \) (see Fig. 3 right hand side). These angles are defined slightly differently from the usual Euler angles: \( \theta_\lambda \) is the angle between \( \vec{R}_{\lambda} \) and the axis \(-\vec{Z}'\) and runs in the interval \( [0, \pi] \); \( \phi_\lambda \) is the angle from the \( \vec{X}' \) axis to the projection of \( \vec{R}_{\lambda} \) on the \( \vec{X}'\vec{Y}' \) plane and runs in the interval \( [0, 2\pi] \). We thus define the vector \( Q \) of the generalized coordinates and the corresponding velocities \( \dot{Q} \)

\[
Q = \{ q_1, q_2, q_3, q_4, q_5, q_6 \} = \{ \theta_\lambda, \phi_\lambda, \theta_\lambda, \phi_\lambda, \theta_\lambda, \phi_\lambda \} . \tag{15}
\]

With these definitions in hand, we have that

\[
\dot{L}_a = \{ \sin \theta_a \cos \phi_a, \sin \theta_a \sin \phi_a, -\cos \theta_a \} , \tag{16}
\]

and similar expressions for \( \dot{L}_a \) and \( \dot{L}_i \). Eq. (16) turns Eqs. 10 into expressions for the \( \vec{R}_{\lambda}(Q) \) and the corresponding velocities \( \vec{V}_{\lambda} = \vec{R}_{\lambda}(Q, \dot{Q}) \). We then conveniently write all the vectors in the \( \{ \vec{X}'\vec{Y}'\vec{Z}' \} \) reference frame in terms of their components in the \( \{ \xi \eta \zeta \} \) frame by means of the rotation matrix \( M \) (Eq. A2), namely \( \vec{R}_{\lambda} = M \vec{\Omega}_{\lambda, \xi \eta \zeta} \) and \( \vec{\rho}_{\lambda} = \vec{R}_{\lambda, \xi \eta \zeta} \).

After noting that \( \vec{\Omega}_{\lambda, \xi \eta \zeta} = \{-\dot{\theta}_{\lambda}, \dot{\phi}_{\lambda} \sin \theta_{\lambda}, \omega_{s} \} \) and performing all the integrals over the three bodies, we finally obtain (Appendix A) the operative expression for \( L(Q, \dot{Q}) \) in the rotating reference frame:

\[
L(Q, \dot{Q}) = T(Q, \dot{Q}) - U(Q) , \tag{17}
\]

where we have defined

\[
T(Q, \dot{Q}) = T_{\text{kin}}(Q, \dot{Q}) + T_{\text{Cor}}(Q, \dot{Q}) , \tag{18}
\]

\[
U(Q) \equiv U_g(Q) + U_{el}(Q) - U_{\text{Cor}}(Q) - U_c(Q) . \tag{19}
\]

The terms entering (17)–(19) are

\[
T_{\text{kin}} = \frac{1}{2} \sum_{\lambda} \left[ m_{\lambda} V_{\lambda}^2(Q, \dot{Q})^2 + I_{\lambda \xi} \left( \dot{\phi}_{\lambda}^2 \sin^2 \theta_{\lambda} + \dot{\theta}_{\lambda}^2 \right) \right] , \tag{20}
\]

\[
T_{\text{Cor}} = \sum_{\lambda} m_{\lambda} \vec{V}_{\lambda}(Q, \dot{Q}) \cdot \left( \vec{\omega} \times \vec{R}_{\lambda}(Q) \right) + \sum_{\lambda} I_{\lambda \xi} \omega_s \dot{\phi}_{\lambda} \sin^2 \theta_{\lambda} , \tag{21}
\]

\[
U_{\text{Cor}} = -\sum_{\lambda} I_{\lambda \xi} \omega_s \cos \theta_{\lambda} \, \omega_s . \tag{22}
\]

To these equations we have to add the expressions (6)–(7) written in terms of \( \vec{R}_{\lambda}(Q) \) through (2) and (10).

Eqs. (17) together with Eqs. (19)–(24) yield the Lagrange function of the model in Fig. 3.

**C. Equilibrium positions and second-order expansion**

During normal and successful operation of the GGG rotor only very small amplitude motions take place. The Lagrange function (17) can thus be expanded to second order in \( \{ Q, \dot{Q} \} \) around the equilibrium solution \( \{ Q^0, \dot{Q} = 0 \} \), \( Q^0 = \{ \theta^0_1, ..., \theta^0_6 \} \) to derive linearized equations of motion.

In order to do this, we first determine the equilibrium positions from the equation

\[
\frac{\partial U}{\partial q_j} = 0 \quad j = 1, ..., n . \tag{22}
\]

We then use the physical assumption that during the motion, the \( Q \)'s are slightly perturbed from their equilibrium values \( Q^0 \). This results in the substitutions

\[
Q \rightarrow Q^0 + Q \quad (23)
\]

\[
\dot{Q} \rightarrow \dot{Q} \quad (24)
\]

into (17) to obtain a linearized version of the Lagrange function. \( L(Q, \dot{Q}) \) can now be expanded to second order,
where we have introduced the generalized forces to the substitutions (23)-(24), and that the linear terms have cancelled out because of (22). The matrix coefficients $a_{jk}$, $b_{jk}$, and $c_{jk}$ are known functions of the $Q^0$ and of the governing parameters of the system, and in general are to be numerically evaluated.

**D. Linearized equations of motion**

The equations of motion in terms of the known $a_{jk}$, $b_{jk}$, and $c_{jk}$ coefficients are

$$\frac{d}{dt} \frac{\partial \mathcal{L}}{\partial \dot{q}_j} - \frac{\partial \mathcal{L}}{\partial q_j} = F_j, \quad j = 1, \ldots, n$$

(26)

where we have introduced the generalized forces

$$F_j = \sum_{d=1}^{3} \tilde{F}^{\alpha_d} \frac{\partial \tilde{R}_{\alpha_d}}{\partial q_j}$$

(27)

starting from the cartesian components $\tilde{F}^{\alpha_d}$ of the forces acting on each body. The $F_j$ are to be consistently expanded to first order, namely

$$F_j = \sum_{k=1}^{6} a_{jk} q_k + \sum_{k=1}^{6} b_{jk} \dot{q}_k .$$

(28)

By combining Eqs. (26)–(28) together, the equations of motion can be written in a compact matrix form as

$$\mathbb{M} \ddot{Q} = \mathbb{S} \begin{pmatrix} Q \\ \dot{Q} \end{pmatrix} ,$$

(29)

with the obvious notation $\ddot{Q} = \{ \ddot{q}_1, \ldots, \ddot{q}_6 \}$. In Eq. (29), $\mathbb{M}$ is the $n \times n$ ($n = 6$) “mass” matrix composed by the $b_{jk}$ coefficients:

$$\mathbb{M}_{jk} = 2b_{jk} \delta_{jk} + b_{jk} (1 - \delta_{jk}) ,$$

(30)

where the factor of 2 on the diagonal elements is a consequence of the restricted $j < k$ sum in the expansion (29). $\mathbb{S}$ is a $n \times 2n$ matrix containing the $a_{jk}$, $c_{jk}$, $\alpha_{jk}$, and $\beta_{jk}$ coefficients:

$$\mathbb{S} = \mathbb{A}_2 + \mathbb{C}_2 + \mathbb{A}_1 + \mathbb{B}_1 ,$$

(31)

with

$$\mathbb{A}_{2jk} = \mathbb{A}_{2kj} = 2a_{jk} \delta_{jk} + a_{jk} (1 - \delta_{jk}) \quad k \leq n$$

$$\mathbb{A}_{1jk} = \mathbb{A}_{1kj} = \alpha_{jk} \quad k \leq n$$

$$\mathbb{C}_{2jk} = 0 \quad k \leq n$$

$$= -\mathbb{C}_{2kj} = c_{jk} - c_{kj} \quad n < k \leq 2n ,$$

$$\mathbb{B}_{1jk} = 0 \quad k \leq n$$

$$= \mathbb{B}_{1kj} = \beta_{jk} \quad n < k \leq 2n .$$

Note that while $\mathbb{M}$ and the submatrix defined by the first $n = 6$ columns of $\mathbb{A}_2$ is symmetric, the submatrix defined by the second $n = 6$ columns of $\mathbb{C}_2$ is antisymmetric, as expected after inspection of the expansion (29).

For all practical purposes, it is convenient to turn (29) into a more symmetric form involving only first-order time derivatives. To this aim, we define the $2n = 12$-component vector $X$ as

$$X_{2j-1} = q_j \quad j = 1, \ldots, n$$

$$X_{2j} = \dot{q}_j .$$

(36)

By inserting the definition (36) into (29), we finally obtain

$$\dot{X} = AX ,$$

(37)

where $A$ is now the square $2n \times 2n$ dynamical matrix defined from $\mathbb{M}^{-1}$ and $\mathbb{S}$ after inserting rows of zeros:

$$A_{jk} = \begin{cases} (\mathbb{M}^{-1} \mathbb{S})_{j1+\frac{k-1}{2}} & j \text{ even and } k \text{ odd} \\ (\mathbb{M}^{-1} \mathbb{S})_{j7+\frac{k-1}{2}} & j \text{ odd and } k = j + 1 \\ 0 & j \text{ odd and } k \neq j + 1 . \end{cases}$$

(38)

The relations (29)–(38) are central equations, written in a form amenable for numerical evaluation. The eigenvalues of the $A$ matrix (38) correspond to the normal modes of the rotor, and the solution of the set of differential equations (37) completely determines the small-amplitude dynamical behavior of the rotor modelled in Fig. 6. Before turning to the description of the numerical method, we introduce rotating and non-rotating damping.

1. Rotating and non-rotating damping

By means of (29)–(38) we can in principle introduce any known force determining the dynamical behavior of the rotor. In the following we include dissipative forces $\mathcal{R}_R$ and $\mathcal{R}_{NR}$ due to rotating and non-rotating damping mechanisms respectively (see (20, 21)). The rotating part of the dissipative force is to be ascribed to dissipation of the laminar suspensions. In supercritical rotation, this
kind of dissipation is known to destabilize the system, generating whirl motions. It can be expressed as

\[ R_R(Q, \dot{Q}) = -\Gamma_R a (\dot{L}_a - (\dot{L}_a \cdot \dot{Z'}) \cdot \dot{Z'}) - \sum_{\lambda=a,i} \Gamma_R a (\dot{L}_\lambda - (\dot{L}_\lambda \cdot \dot{R}_a(Q))) \dot{R}_a(Q), \]

(39)

where the velocities \( \dot{L}_\lambda \) are functions of \((Q, \dot{Q})\). Instead, non-rotating damping has the effect of stabilizing a system in supercritical rotation, and can be written as

\[ R_{NR}(Q, \dot{Q}) = -\Gamma_{NR} (\dot{V}_i(Q, \dot{Q}) + \ddot{\omega}_s \times \dot{R}_i(Q)). \]

(40)

Other forces acting on the rotor, such as external disturbances due to instance- to tides and seismic noise, or control forces applied in order to control the rotor dynamics, can also be included, as described in Sec. **IV**.

### IV. THE NUMERICAL METHOD

#### A. General considerations

The simulation method that we have implemented, rigorously follows the derivation outlined in Sec. **III**. We have found very convenient to use the MATLAB environment, with SYMBOLIC TOOLBOX and SIMULINK packages, as it allows us to perform all the needed symbolic calculations and numerical evaluations, together with the analysis of experimental data.

We start from the formal Lagrange function written in a user-friendly way as in \([9, 10]\) and \([11, 12]\) by means of symbolic vector operations. We specify the choice \([13, 14]\) for the generalized coordinates with respect to the \((X'Y'Z')\) reference frame and define accordingly all the vectors entering \( \mathcal{L} \). We then move on to the symbolic computation by linearizing and expanding the Lagrange function as in \([15]\), and define the matrices \( M, A_2, C_2, A_1, B_1, A, \) and \( A \).

Once the system parameters are fixed (see below), the numerical computation is carried out using standard packages to find eigenvalues and eigenvectors of the \( A \) matrix, that are the normal frequencies and modes of the spinning rotor. The \( A \) matrix is then inserted as input to perform the dynamical simulation within standard transfer-function method used in the SIMULINK toolbox.

The advantage of this strategy is apparent, in that it easily allows us to make any changes in the model that correspond to changes in the experiment we would like to test before implementation. Since the number of bodies \( n_b \) and of the generalized coordinates \( n \) are symbolically defined and specified only once, all what is to be done in order to introduce any changes or new features amounts to modifying or add pieces of the Lagrangean after having symbolically written them in terms of vector operations.

The description of the method used to introduce external forces is postponed to Part II of this work, where it is used to evaluate the common mode rejection function. We now turn to listing the system parameters.

#### B. System parameters

The parameters which govern the physics of the GGG rotor are: the geometrical dimensions of the three bodies, their weight, the mounting error \( \epsilon \), the elastic constants, length and anisotropy factor \( \Lambda \) of the three laminar suspensions, the quality factor \( Q \). To these parameters - which are fixed after construction- we must add the spin frequency \( \nu_s = \omega_s/2\pi \), that can be varied in the course of the experiment. The balancing of the beams and the natural period \( T_D \) of oscillation of the test cylinders relative to one another can also be adjusted as discussed earlier by moving small masses along the balance (coupling) arm.

We have inserted as inputs to the numerical calculation all the above parameters as determined in the real GGG instrument. They are listed in Tab. \([13, 14]\) and \([15, 16]\). As for the spin frequency, in the experiment it varies in the range \((0 \leq \nu_s \leq 3.9)\ Hz\) while in the model calculations it can be assumed in a wider range \((0 \leq \nu_s \leq 10)\ Hz\).

The differential period \( T_D \) corresponding to the value \( \Delta L \) listed in Tab. \([13, 14]\) is measured to be 11.7 s and 10.8 s in the X and Y directions respectively. These values are in reasonable agreement with the following simple formula:

\[ T_D = \frac{2\pi}{\sqrt{(K+K_o+K_a)^2 - \frac{g}{2\nu_s \Delta L}}}. \]

(41)

which can be derived from the general equations of motion \([20]\) describing the small oscillations of the \( \theta_\lambda \) angles, in the very simplified case in which the bodies are neither rotating nor subjected to any dissipative or other external forces, except gravity, and under the reasonable assumption that \( \theta_i = \theta_o = 0 \) and that \( \phi_\lambda \)'s are constant, e.g. \( \phi_\lambda = 0 \).

Of the whole set of parameters used, only the anisotropy factor \( \Lambda \) of the suspensions and the construction and mounting error \( \epsilon \) are not measured from the instrument. \( \Lambda \) is tuned, together with the balancing \( \Delta L \), so as to reproduce the natural frequencies of the non-rotating instrument. A conservative value \( \epsilon = 20 \mu m \) is assumed for the offset, and it is checked \emph{a posteriori} not to have any sizable effect on these results.

### V. RESULTS: THE NORMAL MODES

We have solved for the eigenvalues \( \nu_n \) of the matrix \( A \) in \([17, 18]\) using the system parameters listed in Sec. **IV**.

Fig. \([19, 20]\) summarizes our results by plotting the normal modes of the system \((\nu_n \text{ in the non-rotating frame})\) as functions of the spin frequency \( \nu_s = \omega_s/2\pi \) of the rotor. In this figure, theoretical results for \( \nu_n(\nu_s) \)'s are
displayed by the solid lines in the case of zero rotating damping (i.e., no dissipation in the suspensions), and by the open circles in the case of non-zero rotating damping ($Q(\nu_s) = 510$). At zero damping there are 12 lines, 6 horizontal and 6 inclined; starting from the 3 natural frequencies (Sec. II C 2) of the system, we get $3 \times 2 \times 2 = 12$ normal mode lines, a factor 2 being due to anisotropy of the suspensions in the two orthogonal directions of the plane, and the other to the positive and negative sign (i.e., counter-clockwise or clockwise whirl motion). For the non-zero damping case (open circles) a conservative low value $Q(\nu_s) = 510$ has been assumed (see Tab. II), referring to a comparatively large dissipation. This value has been obtained from previous not so favorable measurements of whirl growth, while much higher $Q$ values (namely, much smaller dissipations) are expected (see discussion on this issue in [13], Sec 3). In Fig. 4 to be compared with the above theoretical results, we plot, as filled circles, the experimental results too, finding an excellent agreement between theory and experiments. Since Fig. 4 contains the crucial results of this work, it is worth discussing its main features in detail. The main features are: the comparison with the experiment, the role of damping, the behavior at low spin frequencies, the so-called scissors’ shape, the splitting of the normal modes and the presence of three instability regions.

### A. Comparison with the experiment

In the experiment, the rotor is first accelerated to spin at a given frequency $\nu_s$. Then, the natural modes are excited by means of capacitance actuators (indicated as $OP$ in Fig. 4 in the $X'$ or $Y'$ directions at frequencies close to the natural frequencies $\nu_n^0 \equiv \nu_n(\nu_s = 0)$ of the system at zero spin. The excitation is performed for several (typically ten) fundamental cycles $1/\nu_n^0$ by means of voltages applied to 4 of the 8 outer plates ($OP$ in Fig. 4). The actuators are then switched off, and the bodies’ displacements are recorded as functions of time by means of the read-out described in Sec. III B. Standard data analysis is then performed, by fitting the measurement data to extract oscillation frequencies and damping of the modes.

Experimental data, resulting from averaging over several measurements, are represented as filled circles in Fig. 4. The agreement between theory and experiments is excellent, thus validating the model developed in Sec. III.

In the experimental spectra as well as in the theory, it is found that the amplitudes of the modes in the subcritical region $\nu_s < \nu$ — represented by the inclined lines, with their open and filled circles— are quite small, while non-dispersive modes (the horizontal lines, not varying with the spin frequency) are preferably excited. When the horizontal lines cross the inclined ones, the latter modes can also be excited. Since the excited modes must obviously be avoided in operating the experiment, this information is very useful, in that it is telling us that we should avoid to spin the system at frequencies where these line crossings occur. Even more so, spin frequencies lying in the instability regions must be avoided (see Sec. IV C).
B. Role of damping

We have numerically checked that dissipation present in the system does not significantly shift the natural-mode frequencies. This is apparent in Fig. 4 where the results obtained with damping (open circles) stay on the solid lines obtained in absence of damping. It is worth stressing the this result is especially good because, as discussed above, we have used a low value \( Q(\nu_s) \approx 510 \), corresponding to comparatively large dissipations. As expected, dissipation affects the line-shape of the peaks, making them wider than in absence of damping.

![Diagram](image)

**FIG. 5:** Normal modes of the GGG rotor. On the left hand side we show a zoom from Fig. 4 in the very low spin frequency region, showing in particular the 3 natural frequencies of the system in the zero spin case. On the right hand side, we plot a zoom from Fig. 4 in the small frequency region of both axes, showing the splitting into two lines of the low frequency mode because of anisotropy of the suspensions (the dashed line is the \( \nu_s = \nu \) line as in Fig. 4).

C. Low-frequency limit

At zero spin frequency we have recovered theoretical and experimental results previously obtained for the non-rotating system. On the left hand side of Fig. 4 a zoom from Fig. 4 at very low spin frequencies, we can see that the non-spinning rotor is characterized by three natural frequencies for the instrument with ideally isotropic springs, the three bodies oscillating in a vertical plane. The frequency \( \nu^0 = 0.09 \) Hz corresponds to the differential mode, where the centers of mass of the two test bodies oscillate in opposite phase; the frequencies \( \nu^0 = 0.91 \) Hz and \( \nu^0 = 1.26 \) Hz correspond to common modes, in which the common center of mass of the two test bodies is displaced from the vertical. During rotation, the number of degrees of freedom increases to six, as discussed in Sec. III B, leading to the six lines plotted in the same figure.

We may get a flavor of the \( \nu_s \) dependence of the modes in the \( \nu_s \ll \nu \) limit, by evaluating the natural frequencies of only one spinning cylinder with mass \( m \), moments of inertia \( I_\xi \) and \( I_\zeta \). The cylinder is suspended at distance \( L \) and with offset \( \epsilon \) from a fixed frame by means of a cardanic suspension with isotropic elastic constant \( K \) and length \( l \). The calculation is performed by following the steps outlined in Sec. III with \( n_b = 1 \) and thus \( n = 4 \). After evaluating the \( A \)-matrix (Appendix B) and solving \( \det(A - sI) = 0 \), we obtain the two double solutions

\[
\nu_{n1,2,3,4} = \pm \nu_0^0 \frac{L}{L'}
\]

for the four \( \nu_n (\nu_s/\nu_n \to 0) \) in the non-rotating frame. In Eq. (12), \( \nu_0^0 = (2\pi)^{-1} \sqrt{g/L + Kl^2/mL^2} \) is the natural frequency for the non-spinning point-like mass. \( L' = \sqrt{L^2 + (I_\xi - 2I_\zeta)/m} \) (with \( I_\xi < 0.5mL^2 + I_\zeta \), see Appendix B), takes into account the extended nature of the body, and the ratio \( L/L' \) modifies \( \nu_n \) with respect to \( \nu_0^0 \).

D. Anisotropy

If the suspensions are not isotropic in the two orthogonal directions, as it is indeed the case for our real cardanic suspensions, each natural frequency is expected to split up. This is clearly shown on the right hand side of Fig. 5. It is worth noting that the splitting is larger for \( \nu_0^0 \) because of anisotropy of the suspensions (the dashed line is the \( \nu_s = \nu \) line as in Fig. 4).

E. Scissors’s shape

Fig. 4 shows that each natural frequency of the non-spinning system splits up into two branches at \( \nu_s > 0 \), a lower branch remaining approximately constant and an upper branch increasing with \( 2\nu_s \).

This characteristic scissors’s shape can be traced back to general properties of spinning bodies (see also Part II). We again use the one-cylinder simple case (see Appendix B) to prove this statement. By following the same procedure which has led to Eq. (12) we obtain (see Eq. (11))

\[
\nu_{1,2} = \pm \sqrt{\nu_0^2 - 2\nu_n \nu_0 \frac{L}{L'} L} \simeq \pm \nu_0 \left( 1 - \frac{\nu_n}{\nu_0} \frac{L}{L'} \right) \quad (43)
\]

\[
\nu_{3,4} = \pm \sqrt{\nu_0^2 + 2\nu_n \nu_0 \frac{L}{L'} L} \simeq \pm \nu_0 \left( 1 + \frac{\nu_n}{\nu_0} \frac{L}{L'} \right) \quad , (44)
\]

showing that in the rotating frame \( \nu_n \propto \nu_s \) to zeroth order. After taking the \( \nu_s/\nu_n \to \infty \) limit and tranforming back to the non-rotating frame by means of the substitution \( s_n = 2\pi \nu_n \to 2\pi (\nu_n + i\nu_s) \), we finally have

\[
\nu_{1,3} \simeq \pm \nu_n \frac{L}{L'} \quad (45)
\]

\[
\nu_{2,4} \simeq 2\nu_s \quad . (46)
\]
F. Mode splitting

The two branches may cross at selected frequencies. Crossing and anticrossing of degenerate modes is a very general concept, which applies to a variety of physical systems, from classical to quantum mechanics, from single to many-particle physics. As it is well known [24], splitting of the modes is expected in correspondence of such crossings. In our numerical results we have found all the 15 splittings expected for our system (see Fig. 4). Fig. 6 shows a particular case of anticrossing of two modes.

![Normal modes of the GGG rotor. A zoom from Fig. 4 showing one particular case of anticrossing of two modes.](image)

FIG. 6: Normal modes of the GGG rotor. A zoom from Fig. 4 showing one particular case of anticrossing of two modes.

G. Instability regions

Dynamical instability may occur whenever the values of the natural frequencies are in proximity of the spin frequency. In such regions the oscillation amplitude grows exponentially.

This is a well-known characteristic of rotating machines; in engineering books it is usually described within the simple model of the so-called Jeffcott rotor [21]. The number of instability regions can be predicted from Fig. 4 after drawing the dotted-dashed line \( \nu = \nu_s \). We have found indeed three instability regions. Fig. 4 displays in detail the one at the lowest frequency; as shown in Fig. 4 the two at higher frequencies are found to be wider and closer to each other. These theoretical results do explain why in the experiment we can increase the spin frequency and cross the low frequency instability region easily, while it is much more difficult to cross the frequency range \( 0.9 \rightarrow 1.3 \, \text{Hz} \). In the past we solved this problem by designing and installing passive dampers to be switched on from remote just before resonance crossing, and then turned off at higher spin frequencies; the least noisy was a special, no oil damper described in [25], p. 45. Later on the GGG rotor imperfections have been reduced so that all instability regions can now be crossed, if the crossing is sufficiently fast, without producing any relevant disturbances even in absence of a passive damper. The physical space previously occupied in the vacuum chamber by the passive damper is now used for the inductive power coupler, indicated as \( PC \) in Fig. 1, which provides the necessary power to the rotating electronics and has allowed us to avoid noisy sliding contacts.

![Normal modes of the GGG rotor. The lowest-frequency instability region is zoomed in from Fig. 4.](image)

FIG. 7: Normal modes of the GGG rotor. The lowest-frequency instability region is zoomed in from Fig. 4.

VI. CONCLUDING REMARKS

We have demonstrated that the linearized model set up in Sec. III can quantitatively account for the dynamical response of the GGG rotor, an apparatus designed to test the equivalence principle with fast rotating, weakly coupled, macroscopic, concentric cylinders (Sec. II). The model developed here can be expanded to include external disturbances whose effects need to be taken into account in testing the equivalence principle. A qualitative understanding has been provided, by means of helpful analytical solutions of the simplified model under special limits, of relevant features observed in the simulations as well as in the experimental data.

We have acquired a detailed knowledge of the instrument’s features and the way it works, the main feature being the normal modes of the system (Sec. V) in the whole range of spin frequencies, from subcritical to supercritical regime, and as functions of the governing parameters (see Sec. IV B).

In particular, we have established the location and characteristics of the instability regions; we have verified quantitatively the effects of dissipation in the system, showing that losses can be dealt with and are not a matter of concern for the experiment; we have established the split up of the normal modes into two scissors’s-like branches, distinguishing modes which are preferentially...
excited (the horizontal lines) from those whose spectral amplitudes are typically small (the inclined lines), thus learning how to avoid the spin frequencies corresponding to their crossings, in order not to excite the quiet modes too by exchange of energy; we have investigated the self-centering characteristic of the GGG rotor when in supercritical rotation regime, gaining insight on how to exploit this very important physical property for improving the quality of the rotor, hence its sensitivity as differential accelerometer.

In the following Part II of this work we apply the same model and methods developed here to investigate the common mode rejection behavior of the GGG rotor, a crucial feature of this instrument devoted to detect extremely small differential effects.

Acknowledgments

Thanks are due to INFN for funding the GGG experiment in its lab of San Piero a Grado in Pisa.

APPENDIX A: THE LAGRANGE FUNCTION IN THE ROTATING REFERENCE FRAME

In the following, in order to simplify the notation we drop the $\lambda$ indices everywhere, and restrict our reasoning to only one body. Let us begin with the expression \( T \). After using Eq. (9) into (4), we have

\[
T = \frac{1}{2} \int_{\tau_i} \left[ \ddot{V}^2 + \left( \ddot{\Omega} \times \dot{\rho} \right)^2 + 2 \ddot{V} \cdot \left( \ddot{\Omega} \times \dot{\rho} \right) \right] dm . \tag{A1}
\]

We conveniently represent the vectors $\dot{\Omega} = \dot{\Omega}_{\xi} \xi_{\xi} \xi$ and $\dot{\rho} = \dot{\rho}_{\eta} \eta_{\eta} \eta$ in the $\{\xi \eta \zeta\}$ frame by means of the rotation matrix

\[
\mathbf{M} = \begin{pmatrix}
\sin \phi & \cos \phi \cos \theta & -\sin \theta \cos \phi \\
-\cos \phi & \cos \phi \sin \theta & -\sin \phi \\
0 & \sin \theta & \cos \theta
\end{pmatrix} \tag{A2}
\]

with respect to the $\{X'Y'Z'\}$ reference system.

Thus, by exploiting the properties of the vectorial product and the definition of center-of-mass, namely $\int_{\tau_i} \rho_\zeta = \int_{\tau_i} \rho_n = \int_{\tau_i} \rho_\zeta = 0$, we find the following results for the integrals appearing in Eq. (A1):

\[
\begin{align*}
\frac{1}{2} \int_{\tau_i} \ddot{V}^2 dm &= \frac{1}{2} m \ddot{V}^2 \\
\frac{1}{2} \int_{\tau_i} \left( \ddot{\Omega} \times \dot{\rho} \right)^2 dm &= \frac{1}{2} \sum_\zeta I_{\zeta \zeta} \Omega_\zeta^2 \\
\frac{1}{2} \sum_\zeta I_{\zeta \zeta} \Omega_\zeta^2 &= \frac{1}{2} I \left( \dot{\phi}^2 \sin^2 \theta + \dot{\theta}^2 \right) \\
\int_{\tau_i} \ddot{V} \cdot \left( \ddot{\Omega} \times \dot{\rho} \right) dm &= \left( \ddot{V} \times \ddot{\Omega} \right) \cdot \int_{\tau_i} \ddot{\rho} dm = 0 \\
\int_{\tau_i} \ddot{V} \cdot \left( \ddot{\omega}_s \times \ddot{R} \right) dm &= m \ddot{V} \cdot \left( \ddot{\omega}_s \times \ddot{R} \right) \\
\int_{\tau_i} \ddot{V} \cdot \left( \ddot{\omega}_s \times \dot{\rho} \right) dm &= \left( \ddot{V} \times \ddot{\omega}_s \right) \cdot \int_{\tau_i} \ddot{\rho} dm = 0 \\
\int_{\tau_i} \left( \ddot{\Omega} \times \ddot{\rho} \right) \cdot \left( \ddot{\omega}_s \times \ddot{R} \right) dm &= \left( \ddot{\omega}_s \times \ddot{R} \right) \cdot \left( \ddot{\Omega} \times \ddot{\rho} \right) = 0 \\
\int_{\tau_i} \left( \ddot{\Omega} \times \ddot{\rho} \right) \cdot \ddot{\omega}_s \times \ddot{R} dm &= I \ddot{\omega}_s \ddot{\rho} \sin^2 \theta + I \ddot{\omega}_s \ddot{\rho} \cos \theta \\
\int_{\tau_i} \left( \ddot{\omega}_s \times \ddot{R} \right) \ddot{\omega}_s \cdot \ddot{R} dm &= \frac{1}{2} m \ddot{\omega}_s \cdot \ddot{R}^2 \\
\int_{\tau_i} \left( \ddot{\omega}_s \times \dot{\rho} \right) \ddot{\omega}_s \cdot \ddot{R} dm &= \frac{1}{2} \left[ I \sin^2 \theta + I \cos^2 \theta \right] \omega_s^2 \\
\int_{\tau_i} \left( \ddot{\omega}_s \times \ddot{R} \right) \ddot{\omega}_s \cdot \ddot{R} dm &= \left( \ddot{\omega}_s \times \ddot{R} \right) \cdot \int_{\tau_i} \left( \ddot{\omega}_s \times \dot{\rho} \right) dm = 0 .
\end{align*}
\]

By collecting all these results, one ends up with the final forms (19)-(21) for the original $T$ function (1).

APPENDIX B: THE ONE-CYLINDER SOLUTION

It is useful to study (along the lines of Sec. III) the simplified case of only one spinning cylinder with mass $m$, moments of inertia $I_\xi$ and $I_\zeta$. This amounts to setting $n_0 = 1$ and thus $n = 4$ for the number of generalized coordinates.

The $A$ matrix turns out to be

\[
A = \begin{pmatrix}
0 & 1 & 0 & 0 \\
L_{12} & L_{12} & L_{12} & L_{12} \\
0 & 0 & 0 & 1 \\
L_{44} & L_{44} - L_{44} & L_{44} & L_{44}
\end{pmatrix}, \tag{B1}
\]

where the coefficients of $L$ and $R$ are defined in terms of the system parameters and of the equilibrium positions.
\[ L_{11} = m \omega_s^2 (L \cos 2 \theta_0 + \epsilon \sin \theta_0) \]
\[- m q L \cos \theta_0 - K' \cos 2 \theta_0 + (I_\xi - I_\zeta) \omega_s^2 \cos 2 \theta_0 \]
\[- I_\zeta \omega_s^2 \cos \theta_0 \]
\[ L_{22} = m L^2 + I_\xi \]
\[ L_{33} = m \omega_s^2 \epsilon L \sin \theta_0 \]
\[ L_{44} = (m L^2 + I_\xi) \sin^2 \theta_0 \]
\[ L_{14} = L_{41} = I_\xi \omega_s \sin 2 \theta_0 - m \omega_s \epsilon L \cos \theta_0 \]
\[ + m \omega_s^2 L^2 \sin 2 \theta_0 \]
\[ L_{23} = L_{32} = -m \omega_s \epsilon L \cos \theta_0 , \]
\[ \theta_0, \phi_0 \text{ as} \]

and
\[ R_{12} = - (\Gamma_R + \Gamma_{NR}) L \]
\[ R_{13} = - \Gamma_{NR} \omega_s L \cos \theta_0 \]
\[ R_{31} = - \Gamma_{NR} \omega_s L \sin \theta_0 \]
\[ R_{34} = - (\Gamma_R + \Gamma_{NR}) L^2 \sin^2 \theta_0 . \]

In the case of negligible dissipation, the eigenvalue equation \( \det(A - sI) \) for \( s = 2 \pi i \nu \) reads
\[ s^4 - s^2 (a_{21} + a_{43} + a_{24} a_{42}) + a_{21} a_{43} = 0 . \] (B6)

In the \( \omega_s \gg \omega_n \) limit, the equilibrium solutions are
\[ \theta_0 \approx \frac{\epsilon L}{L^2} \left[ 1 + \left( \frac{L'}{L} \right)^2 \left( \frac{\omega_n^0}{\omega_s} \right)^2 \right] , \quad \phi_0 = 0 , \] (B7)

where \( L' = \sqrt{L^2 + (I_\xi - 2 I_\zeta) / m}, I_\xi < 0.5 mL^2 + I_\xi \), and
\[ \tilde{\omega}_n^0 = \sqrt{\frac{g}{L} + \frac{K I^2}{m L^2}} \] (B8)

is the natural frequency of the point-like mass. Eq. (B6) becomes then
\[ s^4 + 2 s^2 \omega_s^2 \left[ 1 + \left( \frac{\omega_n^0}{\omega_s} \right)^2 \right] + \omega_s^4 \left[ 1 - 2 \left( \frac{\omega_n^0}{\omega_s} \right)^2 \right] = 0 , \] (B9)

where we have defined the natural frequency of the cylinders mass as \( \omega_n^0 \equiv (L' / L) \tilde{\omega}_n^0 \).

In the \( \omega_s \ll \omega_n \) limit, the eigenvalues equation becomes instead
\[ s^4 + 2 s^2 \left( \frac{L'}{L} \right)^2 \tilde{\omega}_n^{02} + \left( \frac{L'}{L} \right)^4 \tilde{\omega}_n^{04} = 0 . \] (B10)

Eqs. (B9) - (B10) are used to derive the results (12)-(16) in the main text.

**APPENDIX C: THE SELF-CENTERING**

This Appendix is devoted to a key feature of the GGG experiment, namely the concept of self-centering of the rotor in supercritical rotation. Let us analyze the one-cylinder case, by numerically integrating the equations of motion in the presence of non-rotating damping, to make the rotor asymptotically stable (Sec. III D). Fig. 8 shows the resulting motion of the cylinder in the horizontal plane of the rotating reference frame: its center-of-mass spirals inward towards an equilibrium position much closer to the origin, i.e. to the rotation axis. The equilibrium position always lies in the same direction as the initial offset vector \( \vec{\epsilon} \), which in this simulation was assumed to be in the \( X' \) direction. The center of mass of the cylinder will eventually perform small-amplitude oscillations around the asymptotic value \( \{ X'_0 = \epsilon - L \sin \theta_0, Y'_0 = 0 \} \).

![FIG. 8: Self-centering of one cylinder in the presence of non-rotating damping. Simulated \( X'(t) - Y'(t) \) plot showing the motion of the center of mass of the cylinder in the rotating reference frame (one cylinder model, \( \nu_s = 5 \text{ Hz} \). The center of mass spirals inward from the initial offset value and large initial oscillations to a final value, much closer to the rotation axis.](image)

In the limit of small angles we obtain
\[ \theta_0 \approx \pm \frac{\epsilon}{L} \left[ \frac{1}{(L'/L)^2 - (\omega_n / \omega_s)^2} \right] , \] (C1)

with
\[ \phi_0 = 0 (\pi) \] (C2)

in the case of the lower (upper) sign in Eq. (C1), respectively (angles defined as in Fig. 4). The cylinder’s center of mass is eventually located at a distance
\[ \Delta X \approx \epsilon \pm L \theta_0 = \epsilon - \left[ \frac{\epsilon}{(L'/L)^2 - (\omega_n / \omega_s)^2} \right] \] (C3)

from the rotation axis.

In Fig. 8 we plot, as function of the spin frequency \( \nu_s \), the self-centering distance \( \Delta X \) in the one-cylinder case discussed above, and in the point mass case. According to the previous Appendix, if \( L' \neq L \) we have the cylinder, while if \( L = L' \) we have the point mass. The two curves are worth comparing. They have a similar behavior till the resonance peak (in this case, at about \( \nu_s \approx 1 \text{ Hz} \)); the distance from the rotation axis remains constant till, at spin frequencies slightly below the natural one, it starts increasing showing a typical peak at the resonance. For the cylinder and the point mass the
peaks are slightly shifted. The constant value can be obtained from Eq. (C5) in the limit of small spin frequencies \( \omega_s \ll \omega_n \), finding

\[
\Delta X \simeq \epsilon \quad \text{(C4)}
\]

We can also recover the position and relative shift of the resonance peaks in the two cases from the values \( \nu^p \) (the spin frequency at the peak) taken by the poles of \( \Delta X \) in Eq. (C5), namely

\[
\nu^p = \pm \frac{L}{L'} \nu_n . \quad \text{(C5)}
\]

Thus, the position of the peaks is dictated by the natural frequency \( \nu_n \), while the shift is due to the difference between \( L \) and \( L' \).

At rotation speeds above the resonance, and in highly supercritical regime \( \omega_s \gg \omega_n \), the behavior of the cylinder and that of the point mass are remarkably different.

![FIG. 9: Self-centering of one cylinder in the presence of non-rotating damping. The distance \( \Delta X \) of the center of mass of the cylinder from the rotation axis is plotted as function of the spin frequency \( \nu_s \), in agreement with Eq. (C5). The same distance in the case of a point mass is plotted as dashed line. See text for comments on their comparison.](image)

For the cylinder, \( \Delta X \) drops to a minimum and then saturates at a constant value, while for the point mass it keeps decreasing monotonically. The minimum for the cylinder is related to the presence of a zero in Eq. (C5), namely

\[
\nu_s^2 = \pm \frac{L}{\sqrt{L^2 - L'^2}} \nu_n , \quad \text{(C6)}
\]

which is valid only if \( L' > L \). Instead, for the point mass we have the finite value \( \Delta X = \epsilon (1 - \omega_s^2/\omega_n^2) \). Note that the position of the minimum shifts towards higher spin frequencies as \( L' \to L \), namely, as the finite cylinder case approaches a point mass. In the limit \( \omega_s \gg \omega_n \) (i.e., highly supercritical speeds) Eq. (C3) yields

\[
\Delta X \simeq \epsilon \left[ 1 - \left( \frac{L}{L'} \right)^2 \right] , \quad \text{(C7)}
\]

which explains the saturation to a constant self-centering value in the case of a finite cylinder, whereas a point mass would monotonically approach perfect centering (i.e., \( \Delta X = 0 \)).

In point of fact, it is very interesting to note that \( \Delta X \) depends slightly on the point that we are considering along the cylinder’s axis. In particular, in the limit \( \omega_s \to \infty \), where \( \Delta X \) of the cylinder’s center of mass saturates, the point at distance \( \tilde{L} = L'^2/L \) from the suspension point along the axis has instead perfect self-centering, namely \( \Delta X = 0 \). This is easily seen from Eq. (C3) after substituting \( \epsilon \pm \tilde{L} \theta_0 \) with \( \epsilon \pm \tilde{L} \theta_0 \) and imposing \( \Delta X = 0 \). We plan to exploit this property in order to obtain better self-centering, though it needs further investigation in the actual GGG rotor.

We can consider a plot similar to that of Fig. 9 in the GGG case with two concentric cylinders and a coupling arm, where there are 3 natural frequencies (one differential and two common mode).

It happens that the common mode behavior is similar to that of the one-cylinder case (shown as a solid line in Fig. 9); namely, for each common mode frequency there is a resonance peak and a minimum peak. Instead, the differential frequency behavior is similar to that of a point mass (shown as a dashed line in Fig. 9). This latter fact is because in the differential mode the coupling arm oscillates and the cylinders’ centers of mass move in the horizontal plane with opposite phase, while \( \theta_{i,o} = 0 \); under these conditions, their moment of inertia is irrelevant in determining the dynamics, which therefore is very much alike the case of a point mass. As a result, the \( \Delta X \) of the GGG rotor for intermediate values of the spin frequency is characterized by: one peak at low frequency, in correspondence to the differential mode, and two peaks and two minima in correspondence to the common modes. Instead, in the limit of very low and very high spin frequencies, it has a behavior similar to that displayed in Fig. 9 depending on the values and directions assumed for the initial offsets of the three bodies.

Thus, in order to obtain the best possible centering of the test cylinders in the GGG rotor, one can either spin at a frequency close to the minima of the common modes, or above both of them, in such a condition that the two cylinders are better centered on their own rotation axes than both of them are, together, in common mode. Self-centering on the rotation axes is very important in order to reduce rotation noise, because we are dealing with rapidly spinning macroscopic bodies and aiming at measuring extremely small effects. The issue therefore needs careful investigation, and to this end realistic numerical simulations of the apparatus are an essential tool.
Finally, concerning the use of supercritical rotors for EP testing, it is worth mentioning a frequently asked question: Would a relative displacement of the test bodies caused by an external force—such as that resulting from an EP violation—be reduced by self-centering in supercritical rotation as it happens for the original offset $\epsilon$? The answer is “No”, because the offset vector is fixed in the rotating frame of the system, while an external force gives rise to a displacement of the equilibrium position of the bodies in the non-rotating reference frame. In the presence of such a force, whirl motion will take place around the displaced position of equilibrium. A numerical simulation, showing this important feature is reported and discussed in [11], PLA paper, p. 176.
