Irrationality of certain $p$-adic periods for small $p$

Frank Calegari∗

October 28, 2018

1 Introduction

Apéry’s proof [11] of the irrationality of $\zeta(3)$ is now over 25 years old, and it is perhaps surprising that his methods have not yielded any significantly new results (although further progress has been made on the irrationality of zeta values [1], [12]). Shortly after the initial proof, Beukers produced two elegant reinterpretations of Apéry’s arguments; the first using iterated integrals and Legendre polynomials [2], and the second using modular forms [3]. It is this second argument that we shall apply to study the irrationality of certain $p$-adic periods, in particular, the $p$-adic analogues of $\zeta(3)$ and Catalan’s constant for small $p$. To relate certain classical periods to modular forms, Beukers considers various integrals of holomorphic modular forms that themselves satisfy certain functional equations (analogous to the functional equation for the non-holomorphic Eisenstein series of weight two). That these integrals satisfy functional equations is a consequence of the theory of Eichler integrals. The periods arise as coefficients of the associated period polynomials. In our setting these auxiliary functional equations are replaced by the notion of overconvergent $p$-adic modular forms [5], [6]. In this guise our $p$-adic periods will occur as coefficients of overconvergent Eisenstein series of negative integral weight. These $p$-adic periods are equal to special values of Kubota–Leopoldt $p$-adic $L$-functions. Thus $\zeta(3)$ is replaced by $\zeta_p(3) = L_p(3, \text{id})$ and Catalan’s constant

$$G = L(2, \chi) = \sum_{n=0}^{\infty} \frac{(-1)^n}{(2n + 1)^2}$$

is replaced by $L_p(2, \chi)$, where $\chi$ is the character of conductor 4. We shall prove that $\zeta_p(3)$ is irrational for $p = 2$ and 3, and that $L_p(2, \chi)$ is irrational for $p = 2$.

2 Elementary Remarks and Definitions

2.1 Irrationality in $\mathbb{Q}_p$

Let $p$ be prime. Let $\| \cdot \|_p$ denote the $p$-adic absolute value normalized by $\|p\|_p = 1/p$, and let $| \cdot |$ denote the Archimedean absolute value. Given $r = a/b \in \mathbb{Q}$, how well can $r$ be approximated $p$-adically by other (distinct) rational integers?

Lemma 2.1 Suppose that 

$$\left\| \frac{a}{b} - \frac{c}{d} \right\|_p \leq \frac{1}{p^n}.$$ 

Then $\max\{|c|, |d|\} \geq p^n/(|a| + |b|)$.

Proof. The inequality above implies that $ad - bc \equiv 0 \pmod{p^n}$. In particular, it must be the case that $|ad - bc| \geq p^n$, and the lemma readily follows. \hfill \Box

An element $\eta \in \mathbb{Q}_p$ is irrational if it does not lie in $\mathbb{Q}$. From Lemma 2.1 we may derive a simple criterion for irrationality.

Lemma 2.2 (Criterion for $p$-adic irrationality) Let $p_n/q_n$ be rational numbers with $q_n$ unbounded and suppose there exists a $\delta > 0$ such that 

$$0 < \left\| \eta - \frac{p_n}{q_n} \right\|_p \leq \frac{1}{\left( \max\{|p_n|, |q_n|\}\right)^{1+\delta}}$$

for sufficiently large $n$. Then $\eta$ is irrational.

2.2 Overconvergent Eisenstein Series and $p$-adic Zeta Functions

Let $B_n$ denote the $n$th Bernoulli number, defined by the identity

$$\frac{x}{2} + \frac{x}{e^x - 1} = \sum_{n=0}^{\infty} \frac{B_n x^n}{n!}.$$ 

It is a classical result of Euler and Riemann that for non-negative integers $k$,

$$\zeta(1 - 2k) = -\frac{B_{2k}}{2k}$$

where $\zeta$ is the Riemann zeta function. Let $\zeta_p^*(s) = (1 - p^{-s})\zeta(s)$. It is a consequence of the Kummer congruences that the values $\zeta_p^*(s)$ at negative odd integers $p$-adically interpolate. In our context these numbers arise as constant terms of Eisenstein series. Let $q = e^{2\pi i \tau}$ and suppose $2k \geq 2$ is an even integer. Let $\sigma_{2k-1}^*(n) = \sum_{d|n} d^{2k-1}$. Then the Eisenstein series:

$$E_{2k}^*(\tau) = \frac{\zeta^*_p(1 - 2k)}{2} + \sum_{n=1}^{\infty} q^n \sigma_{2k-1}^*(n)$$
is a holomorphic modular form of weight $2k$ for the group $\Gamma_0(p)$. The form $E_{2k}$ is related to the more familiar Eisenstein series of level $\Gamma_0(1)$:

$$E_{2k}(\tau) = \frac{\zeta_p(1-2k)}{2} + \sum_{n=1}^{\infty} q^n \sigma_{2k-1}(n)$$

by the relation $E_{2k}(\tau) = E_{2k}(\tau) - p^{2k-1}E_{2k}(p\tau)$. If $2k$ and $2k'$ are integers congruent modulo $p-1$ and close $p$-adically, then the $q$-expansions of $E_{2k}$ and $E_{2k'}$ are highly congruent. Thus by considering certain limits of $q$-expansions one may define $p$-adic Eisenstein series that are $p$-adic modular forms in the sense of Serre [10]. However, one can also make a more precise analytic statement. The usual context in which to view $p$-adic families of $p$-adic eigenforms with finite slope (non-zero $T_p$-eigenvalue) is Coleman’s theory of overconvergent modular forms [5], [6] (see also [3]). This theory is quite extensive and we must be content with the following (very brief) explanation. Holomorphic modular forms are given by sections of certain line bundles over modular curves, and their $q$-expansions are obtained by evaluating at the cusp at infinity. A $p$-adic modular form of integral weight is a section of the same sheaf, except considered only over a certain region of the modular curve defined by points whose corresponding elliptic curve is ordinary (more precisely the connected component of this space containing the cusp at infinity). This region is not open in the sense of the Zariski topology, but rather in the sense of rigid analytic geometry (the analytic geometry of the $p$-adic world). Finally, an overconvergent modular form of integral weight is a $p$-adic modular form which extends as a section to some rigid analytic region of the modular curve strictly containing the (connected component containing infinity of) the ordinary locus. It is precisely this overconvergence which will be the $p$-adic analogue of Beukers’ construction whereby a certain analytic expression $A(z) + \theta B(z)$ converges further for some special value of $\theta$ than for any other.

In general, the weight of a modular form can vary over a rigid analytic space $W$ (weight space) of characters (see [4] p. 27). Let $q = p$ if $p$ is odd and $q = 4$ if $p = 2$. A $\mathbb{C}_p$-point of $W$ corresponds to a map

$$\Lambda = \mathbb{Z}_p[[(\mathbb{Z}/q\mathbb{Z})^{\times} \times (1 + q\mathbb{Z}_p)]] \simeq \lim_{\leftarrow} \mathbb{Z}_p[[(\mathbb{Z}/p^n\mathbb{Z})^{\times}]] \to \mathbb{C}_p.$$ 

The classical even integral weights correspond to the characters that send $a$ with $a \in \lim_{\leftarrow} (\mathbb{Z}/p^n\mathbb{Z})^{\times}$ to $a^{2k}$. Let $W^+$ be the part of weight space consisting of characters $\kappa$ such that $\kappa(-1) = 1$. For $n \geq 1$ let

$$\sigma^*_\kappa(n) := \sum_{d|n} \kappa(d)d^{-1}.$$ 

**Theorem 2.3** There exists a function $\zeta_p(\kappa)$ on $W^+$ which is rigid analytic outside $\kappa = 1$ and has a simple pole at $\kappa = 1$, such that if

$$E_\kappa = \frac{\zeta_p(\kappa)}{2} + \sum_{n=1}^{\infty} \sigma^*_\kappa(n)q^n$$
Then $E_\kappa$ varies rigid analytically over weight space (away from $\kappa = 1$) and for each point $\kappa \in \mathcal{W}^+$ specializes to an overconvergent eigenform. Moreover, if $2k \geq 2$ is an even positive integer and $\kappa$ is the character sending $a$ to $a^{2^k}$ then $E_\kappa = E_{2k}^\ast$.

This theorem in this generality is essentially proved in [5]. By continuity, we may recover the value of $\zeta_p(\kappa)$ at characters $a \mapsto a^{-2n}$ for positive integers $n$ as follows:

**Lemma 2.4** Let $\zeta_p(1 + 2n)/2$ be the constant term of $E_\kappa$ at the character $a \mapsto a^{-2n}$. Then

$$\zeta_p(1 + 2n) = \lim_{k \to n} \zeta(1 - 2k).$$

Where the limit runs over strictly increasing integers $k$ approaching $n$ in $\mathbb{Z}_p$ with the added restriction that $2k \equiv 2n \mod p - 1$.

The added restriction comes from the fact that the characters $a \mapsto a^{2^k}$ and $a \mapsto a^{2k'}$ are close if $2k \equiv 2k' \mod (p - 1)p^n$ for large $n$, as follows from Euler’s version of Fermat’s little theorem. The imposition that $k$ approaches infinity means we can neglect the Euler factor term, which tends to 1.

**Remark.** As with the classical zeta values, not much is known about the arithmetic nature of $\zeta_p(1 + 2n)$. Indeed it could be argued that the situation is worse, as little is known about the following conjecture, even for $n = 1$:

**Conjecture 2.5** For all integers $n > 0$ and primes $p$, the values $\zeta_p(1 + 2n) \neq 0$.

It was the (failed) attempt to prove this conjecture for $n = 1$ that lead to this paper, the idea being that if one can prove that $\zeta_p(3)$ is irrational then one has also shown it is non-zero!

Let $2k$ be a positive even integer $\geq 4$. If $E_{2k}$ the the classical Eisenstein series of weight $2k$ and level $\Gamma_0(p)$ then associated to $E_{2k}$ there is another Eisenstein series, the evil twin $E_{2k}^{\text{evil}}$. The Eisenstein series $E_{2k}^{\text{evil}}$ is classical, cuspidal at the cusp at $\infty$ and has slope $2k - 1$. Explicitly, the evil twin is given by the following formula:

$$E_{2k}^{\text{evil}}(\tau) = E_{2k}(\tau) - E_{2k}(p\tau).$$

Let us consider the specialization $E_{-2k}$ of our Eisenstein family. Let $\theta$ be the operator on $q$ expansions that acts as $q \cdot d/dq = (2\pi i)^{-1}d/d\tau$. Then one can easily compute that

$$\theta^{2k+1}E_{-2k} = E_{2k+2}^{\text{evil}}.$$

Thus we can “almost” reconstruct $E_{-2k}$ from $E_{2k+2}^{\text{evil}}$ by considering

$$E'_{-2k}(\tau) = (2\pi i)^{2k+1} \int \cdots \int E_{2k+2}(d\tau)^{2k+1} \in \mathbb{Q}[[q]]$$
The function $E'_{-2k}$ is holomorphic in a neighbourhood of the cusp $i\infty$, but is not modular (although similar modified forms satisfy some form of functional equation — see [3], p. 273). Actually, for our purposes, we could have introduced the function $E'_{-2k}$ directly without reference to $E^\text{evil}_{2k+2}$. However, by writing down the connection we stress the ties between our method and that of Beukers [3]. Let $\eta \in \mathbb{C}_p$ and consider the expression

$$H = E^*_2(E'_{-2k} + \eta).$$

If $\eta = \zeta_p(1 + 2k)/2$ then $H$ is equal to $E^*_2E_{-2k}$ and is thus an overconvergent modular function of weight 0. For all other $\eta$, however, $H$ is not overconvergent since otherwise $E^*_2$ would be overconvergent of weight 0, which is impossible (this follows from [8], 4.4). Thus we obtain a strictly analytic (over $\mathbb{C}_p$) characterization of $\zeta_p(1 + 2k)$.

Suppose that $X_0(p)$ has genus zero. Then the ordinary locus of $X_0(p)$ containing the cusp at infinity is a rigid analytic disc.

Suppose that $z$ is a classical meromorphic modular form that is a local parameter over the cusp $i\infty$ and has no poles on the component of the ordinary locus of $X_0(p)$ containing $\infty$ (so $z$ is overconvergent). Viewing $z$ first as a complex analytic function, by the inverse function theorem we may expand

$$H = \sum_{n=0}^{\infty} (a_n - b_n \eta) z^n.$$

Now considering this sum $p$-adically, we know that $H$ is overconvergent if and only if $\eta = \zeta_p(1 + 2k)/2$. Thus we expect the radius of convergence to jump at this point, and correspondingly the sequence $a_n/b_n$ to converge $p$-adically to $\zeta_p(1 + 2k)/2$. If we can estimate both the $p$-adic and Archimedean radii of convergence for various $\eta$ we may be able to apply our criterion of irreducibility. In the next section we carry this out in detail for $p = 2$.

### 3 The irrationality of $\zeta_p(3)$ for $p = 2$ and $p = 3$

#### 3.1 $p = 2$

Let $p = 2$. Then $X_0(2)$ has genus zero, and is uniformized by the function

$$f = \frac{\Delta(2\tau)}{\Delta(\tau)} = q \prod_{n=1}^{\infty} (1 + q^n)^{24}.$$

Moreover we note the following facts about $f$ and $X_0(2)$. The curve $X_0(2)$ has two cusps, $i\infty$ and 0. The value of $f$ at these cusps is equal to 0 and $\infty$, respectively. In particular, $f$ is a local uniformizer at the cusp at infinity. The curve $X_0(2)$ has one elliptic point, at $(1 + i)/2$. The value of $f$ at this point is equal to $-2^{-6}$. This can be proved by noting that $f'/f = E^*_2$ and that

$$\frac{E^6_2}{\Delta} = \frac{(1 + 2^6f)^3}{f}.$$
The ordinary locus of (the 2-adic rigid analytic curve) \( X_0(2) \) has two components, given by

\[ \| f \|_2 \leq 1, \quad \| f \|_2 \geq 2^{12}. \]

The Fricke involution permutes these two spaces, as it sends \( 2^{12} f \) to \( 1/f \).

Consider the series

\[ H = E_{2k}^*(E_{-2k} + \eta) = \sum_{n=0}^{\infty} (a_n - b_n \eta) f^n. \]

Since \( f = q + \ldots \) it follows that \( b_n \in \mathbb{Z} \). Since the \( q^n \) coefficient of \( E_{-2k}^* \) lies in \( \mathbb{Z}/n^{2k-1} \) it also follows that \([1,2,\ldots,n]^{2k+1} \) \( a_n \in \mathbb{Z} \), where \([1,2,\ldots,n] \) is the greatest common divisor of 1 up to \( n \).

Let us establish the 2-adic convergence of this series for various values of \( \eta \).

**Lemma 3.1** If \( p = 2 \) and \( \eta = \zeta_p (1 + 2k)/2 \) then the radius of convergence of \( H \) is at least \( 2^{12} \). If \( \eta \neq \zeta_p (1 + 2k)/2 \) then the radius of convergence is at most 1.

**Proof.** If \( \eta = \zeta_p (1 + 2k)/2 \), then \( H = E_{2k}^* E_{-2k} \). Since \( E_{-2k} \) is overconvergent, it extends as a rigid analytic function somewhere into the supersingular annuli. However, it is also a finite slope eigenform of level \( \Gamma_0(2) = \Gamma_0(p) \), and such sections extend far into the supersingular annuli. In particular, by Theorem 5.2 of Buzzard [4], it extends entirely over the supersingular annuli. Thus the radius of convergence is at least \( 2^{12} \). If \( \eta \neq \zeta_p (1 + 2k)/2 \), then \( H \) is not overconvergent. Thus it cannot extend into the supersingular annuli and the radius of convergence is at most 1.

From this lemma we may approximate \( \zeta_p (1 + 2k)/2 \), since when \( \eta = \zeta_p (1 + 2k)/2 \) the radius of convergence guaranteed by the previous lemma implies that

\[ \| a_n - b_n \eta \|_2 \ll 2^{-(12-\epsilon)n}. \]

for any \( \epsilon > 0 \) and sufficiently large \( n \). Since \( b_n \in \mathbb{Z} \), and since \( E_{2k}^* \) is not overconvergent of weight 0, it follows as in the proof of Lemma 3.1 that the 2-adic valuation of \( b_n \) grows slower than any power of 2. It follows that (for \( \epsilon > 0 \) and \( n \gg 0 \) as above):

\[ \left\| \zeta_2 (1 + 2k) - \frac{2a_n}{b_n} \right\|_2 \ll 2^{-(12-\epsilon)n}. \]

Now let us turn to the Archimedean valuations of \( a_n \) and \( b_n \). Our arguments here are completely analogous to those of Beukers [3]. By considering \( f \) at the cusps and the elliptic points we see that the radius of convergence of \( f \) will be equal to the first branching value, which occurs at \( f((1+i)/2) = -1/2^6 \). Thus we obtain the estimates:

\[ |a_n|, |b_n| \ll 2^{(6+\epsilon)n} \]
for all $\epsilon > 0$ and sufficiently large $n$ (depending on $\epsilon$). The coefficient $a_n$ is not an integer, however. If we write $a_n = c_n/d_n$ then since $[1, 2, \ldots, n]^{2k+1} a_n \in \mathbb{Z}$ it follows from the prime number theorem that (with the usual restrictions on $\epsilon$ and $n$) that

$$|d_n| \leq [1, 2, \ldots, n]^{2k+1} \ll e^{(2k+1+\epsilon)n}.$$ 

Consequently, if we write $2a_n/b_n = p_n/q_n$ where $p_n$ and $q_n$ are integers, then

$$|p_n| \leq |c_n| = |d_n| |a_n| \ll 2^{(6+(2k+1)/\log 2+\epsilon)n}, \quad |q_n| \leq |d_n| |b_n| \ll 2^{(6+(2k+1)/\log 2+\epsilon)n}.$$ 

Combining this with our 2-adic estimates we have proven the following.

**Lemma 3.2** There exists integers $p_n, q_n$ such that $q_n$ approaches infinity, and such that if

$$\theta = \frac{12 \log 2}{6 \log 2 + 2k + 1}$$

then

$$0 < \left\| \zeta_2(1+2k) - \frac{p_n}{q_n} \right\|_2 \leq \frac{1}{(\max\{|p_n|, |q_n|\})^{\theta-\epsilon}}$$

for sufficiently large $n$.

**Proof.** This follows from the estimates we have proven so far, it sufficing to prove that $a_n - \theta b_n \neq 0$ for sufficiently large $n$. Assume otherwise. Then $H$ is a polynomial in $f$. In particular $\zeta_p(1+2k) \in \mathbb{Q}$, $H$ has coefficients in $\mathbb{Q}$ and $E_{-2k}$ is a classical meromorphic eigenform of weight $-2k$. From the $q$-expansion we may determine that $E_{-2k}$ has no poles away from the cusps, and a pole of order at most 1 at $\tau = 0$. It follows that $H$ is linear in $f$, which contradicts the fact that $a_2/b_2 \neq a_3/b_3$. \qed

As a corollary of this, we prove:

**Theorem 3.3** If $p = 2$ then $\zeta_2(3) \notin \mathbb{Q}$.

**Proof.** If $k = 1$ then $\theta = 1.1618804316 \ldots > 1$. Thus we may apply our criterion for irrationality. \qed

If $k = 2$ then $\theta = 9.081638111 < 1$ so we cannot establish irrationality of $\zeta_2(5)$ (nor indeed $\zeta_2(1+2k)$ for any other $k \geq 2$).

The first few $a_n$ and $b_n$ are given as follows:

$a_n : 0, 1, 1, -8072/27, 160841/9, -1088512616/1125, -1088512616/1125 \ldots$

$b_n : 1, 24, -552, 19392, -810024, 37210944, -1815620160 \ldots$

They are the 2-adic analogue of Apéry’s sequences $\{a_n, b_n\}$. 

7
3.2 $p = 3$

The same technique can also be applied to other $p$ when $X_0(p)$ has genus zero, where $f$ is chosen to be $(\Delta(p\tau)/\Delta(\tau))^{1/(p-1)}$. In this manner we prove the following:

**Theorem 3.4** If $p = 3$ then $\zeta_p(3) \notin \mathbb{Q}$.

**Proof.** The construction works as for $p = 2$. It suffices to determine the various radii of convergence. If $f = (\Delta(p\tau)/\Delta(\tau))^{1/p}/(p-1) = \Delta(\tau)$, the components of the ordinary locus are given by $\|f\|_3 \leq 1$ and $\|f\|_3 \geq 3^6$. The curve $X_0(3)$ has two cusps 0 and $i\infty$ at which $f$ has a pole and zero respectively. There is one elliptic point at $1/2 + \sqrt{-3}/6$, at which point $f$ takes the value $-3^{-3}$. Thus one finds that

$$\theta = \frac{6}{3 + 3/\log 3} = 1.0469892839 \ldots > 1,$$

and thus by the criterion of irrationality we are done. \qed

Although the proof succeeds for $p = 3$, it fails for the other primes where $X_0(p)$ has genus zero ($p = 5, 7$ and 13). For example, for $p = 5$ we find that

$$\theta = \frac{3}{3/2 + 3/\log 5} = 0.8917942081 < 1.$$

4 The 2-adic Catalan’s Constant

There can be no $p$-adic analogue of Apéry’s results for $\zeta(2)$, since $\zeta_p(2) = 0$ for all $p$. However, we may still study other $p$-adic $L$-values, in particular the analogue of Catalan’s constant:

$$G := \frac{1}{1^2} - \frac{1}{3^2} + \frac{1}{5^2} - \frac{1}{7^2} + \ldots$$

In this context we should study Eisenstein series of odd weight and non-trivial character. Let $p = 2$. Let $\chi$ be the character of conductor 4. Then $L(2, \chi) = G$, whilst for non-negative $k$,

$$L(-2k, \chi) = \frac{E_{2k}}{2}$$

where $E_{2k}$ is the $2k$th Euler number. Moreover, there exists for each odd positive integer an Eisenstein series $F_{2k+1} \in S_{2k+1}(\Gamma_1(4), \chi)$ given by the following $q$-expansion:

$$F_{2k+1} = \frac{L(-2k, \chi)}{2} + \sum_{n=1}^{\infty} q^n \left( \sum_{d|n} d^{2k} \chi(d) \right) = \frac{L(-2k, \chi)}{2} + \sum_{n=0}^{\infty} \frac{q^{(2n+1)}(-1)^n(2n+1)^{2k}}{(1-q^{2n+1})}.$$ 

Indeed, $F_{2k+1}$ is nothing but the 2-adic specialization of $E_{\kappa}$ to weights of the form $\chi \cdot (a \mapsto a^{2k+1})$, which are even since $\chi(-1) = -1$. Since

$$F_{-1} = \frac{L_2(2, \chi)}{2} + \sum_{n=0}^{\infty} \frac{q^{(2n+1)}(-1)^n}{(2n+1)^2(1-q^{2n+1})},$$
We shall consider the function
\[ H = F_1(F'_1 + \eta), \]
where \( F'_1 \) is holomorphic on the complex upper half plane and formally given by the \( q \)-expansion
\[ F'_1 = \sum_{n=0}^{\infty} \frac{q^{(2n+1)}(-1)^n}{(2n+1)^2(1-q^{2n+1})}. \]
If \( \eta = L_2(2, \chi)/2 \) then \( F'_1 + \eta = F'_{-1} \) is overconvergent (and thus so is \( H \)), and otherwise it is not. Our arguments now proceed in a very similar manner to those of \( \zeta_p(3) \).

The curve \( X_1(4) \) has genus zero, no elliptic points, and three cusps corresponding to \( i\infty, 1/2 \) and \( 0 \). A uniformizer is given by the function
\[ z = \left( \frac{\Delta(4\tau)}{\Delta(\tau)} \right)^{1/3} = q \prod_{n=1}^{\infty} (1+q^n)^8(1+q^{2n})^8. \]
The function \( z \) vanishes at the cusp at infinity, has a pole at the cusp at 0, and equals \(-2^{-4}\) at the cusp \( 1/2 \). The Fricke involution sends \( 2^8z \) to \( 1/z \), and the component of the ordinary locus containing infinity is \( \|z\|_2 \leq 1 \). If we write
\[ H = \sum_{n=0}^{\infty} (a_n - b_n \eta) z^n \]
the singularity obtained by inverting \( z \) occurs at \( z = -2^{-4} \) and thus we obtain the Archimedean estimates
\[ |a_n|, |b_n| \ll 2^{(4+\epsilon)n} \]
for all \( \epsilon > 0 \) and \( n \gg 0 \) depending on \( \epsilon \). Furthermore it is clear that
\[ b_n \in \mathbb{Z}, \quad [1, 2, \ldots, n]^2 a_n \in \mathbb{Z} \]
Thus if \( 2a_n/b_n = p_n/q_n \) one obtains the estimates
\[ |p_n|, |q_n| \ll 2^{(4+2/\log 2+\epsilon)n}. \]

We now study the 2-adic radii of convergence for various \( \eta \).

**Lemma 4.1** If \( \eta = L_2(2, \chi)/2 \) then the radius of convergence of \( H \) is at least \( 2^8 \). If \( \eta \neq L_2(2, \chi)/2 \) then the radius of convergence is at most 1.

**Proof.** If \( \eta \neq L_2(2, \chi)/2 \) then \( H \) is not overconvergent so the radius of convergence is at most 1. Suppose that \( \eta = L_2(2, \chi)/2 \). Then \( F_{-1} = F'_1 + \eta \) is an overconvergent finite slope eigenform of level \( \Gamma_1(4) \). Once more we may appeal to the convergence results of Buzzard \([4]\), in particular, Corollary 6.2, to conclude that \( F_{-1} \) extends not only over all of the supersingular region but everywhere over of \( X_1(4) \) except (possibly) the component of the ordinary locus containing \( 0 \), which is \( \|z\|_2 \geq 2^8 \). \( \Box \)

Combining these results, we conclude the following:
Theorem 4.2 There exists integers $p_n, q_n$ such that $q_n$ approaches infinity, and such that if

$$\theta = \frac{8 \log 2}{4 \log 2 + 2} = 1.1618804316 \ldots > 1$$

then

$$0 < \left\| L_2(2, \chi) - \frac{p_n}{q_n} \right\|_2 \leq \frac{1}{(\max\{|p_n|, |q_n|\})^{\theta - \epsilon}}$$

for sufficiently large $n$. In particular, $L_2(2, \chi)$ is irrational.

We write down the first few terms $a_n, b_n$:

$$a_n : 0, 1, -3, 116/9, -331/9, -99116/225, 3133076/225 \ldots$$

$$b_n : -1, -4, 28, -272, 3036, -36624, 464368 \ldots$$

Note that

$$2 \cdot \frac{a_6}{b_6} = \frac{783269}{13060350} = 2^{-1} + 1 + 2^2 + 2^3 + 2^5 + 2^6 + 2^7 + 2^9 + 2^{13} + 2^{18} + \ldots$$

already agrees with $L_2(2, \chi)$ to order $2^{34}$. As remarked in [9], the generating function for $b_n$ automatically satisfies a second order differential equation. Indeed one finds that $a_n$ and $b_n$ satisfy the Apéry like recurrences:

$$(n+1)^2 u_{n+1} = (4 - 32n^2)u_n - 256(n-1)^2 u_{n-1}.$$ 

If $u_1 = -4$ and $u_2 = 28$ then $u_n = b_n$, whilst if $u_1 = 1$ and $u_2 = -3$ then $u_n = a_n$.
