Since the discovery of high-temperature superconductivity in copper oxide materials, there have been sustained efforts to understand the origins of this phase and discover new cuprate-like superconducting materials. One prime materials platform has been the rare-earth nickelates and, indeed, superconductivity was recently discovered in the doped compound Nd6Sr3NiO12 (ref. 7). Undoped NdNiO4 belongs to a series of layered square-planar nickelates with chemical formula Ndₙ₊₁NiO₂₀₋₂n and is known as the ‘infinite-layer’ (n = ∞) nickelate. Here we report the synthesis of the quintuple-layer (n = 5) member of this series, Nd₅NiO₁₂, in which optimal cuprate-like electron filling (d⁰⁺) is achieved without chemical doping. We observe a superconducting transition beginning at ~13 K. Electronic structure calculations, in tandem with magnetoresistive and spectroscopic measurements, suggest that Nd₅NiO₁₂ interpolates between cuprate-like and infinite-layer nickelate-like behaviour. In engineering a distinct superconducting nickelate, we identify the square-planar nickelates as a new family of superconductors that can be tuned via both doping and dimensionality.

Attempts to construct materials that are iso-electronic and isostructural to the cuprates as candidate superconducting systems have spanned more than three decades. In this context, nickelate materials have been of enduring interest due to the proximity of nickel and copper in the periodic table; furthermore, Ni⁴⁺ has the same d⁰⁺ electron count as Cu²⁺. With continued understanding of the cuprates superconductivity—including, for example, a prominent orbital polarization, strong transition metal–oxygen hybridization or a quasi-two-dimensional square lattice—general attention to nickelates has been refined to specific proposals for LaNiO₃/NaMIO superlattices (M, trivalent cation) and Laₙ₊₁SrₙNiO₂₀ (ref. 7). To date, superconductivity has not been realized in any of these originally proposed materials. Most recently, however, Sr-doped NdNiO₄, the so-called ‘infinite-layer’ nickelate, has been shown to be superconducting, with a dome-like doping dependence to the superconducting transition temperature, Tc, centred around d⁰⁺ nickel filling.

Following this observation of superconductivity in Sr-doped NdNiO₄, there has been considerable interest in determining how ‘cuprate-like’ these infinite-layer nickelates are. For example, while the cuprates are often described by a single-band Hubbard model, electronic structure descriptions of the infinite-layer nickelates invoke multiband models, including hybridisation with the rare-earth 5d bands. Infinite-layer nickelates also seem to exhibit a much larger charge-transfer energy than their cuprate counterparts. Experimentally, the synthesis of these compounds remains challenging and to date there are only three independent reports of superconductivity, all in the chemically doped infinite-layer compound. These extended difficulties in reproducing nickelate superconductivity have generated a flurry of questions involving the synthetic challenges, the substrate–film interface, and, most importantly, whether there exists an entire family of nickelate superconductors beyond compounds accessible through isovalent cation substitution.

Here, we note that NdNiO₄ is the end, or ‘infinite’ (n = ∞), member compound of the broader layered Rₙ₊₁NiO₂₀₋₂n, (R, trivalent rare-earth cation, n > 1) series. This family of layered materials possesses quasi-two-dimensional NiO planes in a square-planar coordination with rare-earth fluorite blocking slabs interleaved every n nickel layers. These square-planar compounds are obtained via oxygen deintercalation from the corresponding parent perovskite RₙNiO₃ (n = ∞) and Ruddlesden–Popper Rₙ₊₁NiO₂₀₋₂n (n ≠ ∞) phases (Fig. 1b). As shown in Fig. 1a, the Rₙ₊₁NiO₂₀₋₂n series can be mapped onto the cuprate phase diagram in terms of the nickel 3d electron count using formal valence-counting rules (Supplementary Note 1), where the end member NdNiO₄ has d⁰⁺ (Ni⁴⁺) filling. The trilayer RₙNiO₃ (n = 3, R = La or Pr) nickelates have been reported as close cuprate analogues, although superconductivity has not been observed. Both LaₙNiO₃ and PrₙNiO₃ exhibit strong orbital polarization with a large cuprate-like magnetic superexchange, strengthening the connection to the cuprate phase diagram. These trilayer nickelates have an average d⁰⁺ (Ni⁴⁺) filling across the nickel planes (note that in multilayer cuprates, NMR experiments have shown that there is a layer-resolved doping profile), lying in the ‘overdoped’ regime of the cuprate phase diagram. Meanwhile,
the ‘quintuple-layer’ compound $\text{R}_n\text{Ni}_n\text{O}_{3n+2}$ ($n = 5$) with optimal nickel $d^{8-9}$ filling falls directly at the optimal doping to align with the cuprate phase diagram and is thus an appealing target to search for further nickelate superconductivity.

We synthesized the square-planar layered compound $\text{Nd}_5\text{Ni}_6\text{O}_{12}$ ($n = 5$) with optimal nickel $d^{8-9}$ filling from its Ruddlesden–Popper parent phase $\text{Nd}_2\text{Ni}_3\text{O}_7$. We additionally synthesized the ‘over-doped’ layered compound $\text{Nd}_3\text{Ni}_4\text{O}_{12}$ ($n = 3$) with $d^{6-7}$ filling, whose Ruddlesden–Popper parent phase $\text{Nd}_2\text{Ni}_3\text{O}_7$ has been well characterized in the bulk, to benchmark our studies\textsuperscript{20,21}. First, we employed reactive–oxide molecular beam epitaxy to stabilize epitaxial thin films of the oxidized Ruddlesden–Popper $\text{Nd}_n\text{Ni}_n\text{O}_{3n+1}$ compounds on (110)-oriented $\text{NdGaO}_3$ substrates (Methods and Supplementary Note 2). This was followed by an ex-situ $\text{CaH}_2$-assisted topotactic reduction to deintercalate oxygen and convert the films into the square-planar ($\text{Nd}_{n-1}\text{Ni}_{n-1}\text{O}_{3n-2}$) phase (Methods), as has been performed in the infinite-layer compounds\textsuperscript{11,12}.

Cross-sectional transmission electron microscopy (STEM) images of the $n = 5$ parent Ruddlesden–Popper phase $\text{Nd}_5\text{Ni}_5\text{O}_{16}$ and the reduced compound $\text{Nd}_5\text{Ni}_5\text{O}_{15}$ are shown in Fig. 2a–c. Atomic-resolution high-angle annular dark-field (HAADF) and annular bright-field (ABF) images of well-ordered regions confirm both the shortening of the $c$ axis lattice constant and the removal of apical oxygen in the neodymium planes from the $\text{Nd}_5\text{Ni}_5\text{O}_{16}$ (Fig. 2a) to the $\text{Nd}_5\text{Ni}_5\text{O}_{15}$ phase (Fig. 2b). As shown in Fig. 2c, elemental mapping by electron energy loss spectroscopy (EELS) illustrates the quintuple-layer structure with the neodymium fluorite layers of the $\text{Nd}_5\text{Ni}_5\text{O}_{15}$ film. Similar to superconducting infinite-layer nickelates\textsuperscript{12,13}, these samples also show regions of secondary or defect inclusions in addition to the layered nickelate phase (Supplementary Note 3 and Supplementary Figs. 4–7). The structural coherence at the bulk scale of both $n = 3$ and $n = 5$ Ruddlesden–Popper and square-planar phases was probed with X-ray diffraction. X-ray diffraction scans in Fig. 2d display the presence of superlattice peaks demonstrating ordering of the Ruddlesden–Popper structure. Upon reduction, we observed a rightward shift of the superlattice peaks in the diffraction spectra, corresponding to a compression of the out-of-plane lattice constants from $c = 42.5$ Å to $c = 38.8$ Å for $\text{Nd}_5\text{Ni}_6\text{O}_{12}$ and $c = 27.4$ Å to $c = 25.4$ Å for $\text{Nd}_3\text{Ni}_4\text{O}_{12}$, which is consistent with the STEM imaging.

Electronic characterization via EELS (Supplementary Note 3 and Supplementary Fig. 8) and X-ray absorption spectroscopy (XAS) (Supplementary Note 5 and Supplementary Fig. 11) further confirm reduction to the square-planar phase. The intense pre-peak at the O K-edge in $\text{Nd}_5\text{Ni}_5\text{O}_{16}$ associated with oxygen 2$p$ orbitals hybridized with (formal) nickel 3$d^{9-10}$ states is altered upon reduction\textsuperscript{12}. A shoulder with weaker spectral weight emerges at higher energies in $\text{Nd}_5\text{Ni}_6\text{O}_{12}$, which is consistent with the hybridized nickel 3$d^{10-11}$–oxygen 2$p$ states. This has been seen in bulk compounds\textsuperscript{11,12}, as well as in infinite-layer compounds that achieve similar nickel filling through chemical doping\textsuperscript{12}.

The electronic properties of the layered nickelate thin films are shown in Fig. 3. Figure 3a shows the temperature-dependent resistivities of the as-synthesized Ruddlesden–Popper compounds before reduction. The $\text{Nd}_5\text{Ni}_5\text{O}_{16}$ film exhibits a resistivity kink at $\sim 155$ K, which is probably due to charge density wave formation\textsuperscript{11,12}. Our $\text{Nd}_5\text{Ni}_5\text{O}_{15}$ Ruddlesden–Popper films all display a metal-to-insulator transition with a weak hysteresis reminiscent of the first-order transition of the perovskite $\text{NdNiO}_3$. Upon reduction, $\text{Nd}_5\text{Ni}_5\text{O}_{15}$ exhibits metallic behaviour similar to that observed in the infinite-layer $\text{NdNiO}_3$ (ref. \textsuperscript{13}) and trilayer $\text{PrNiO}_3$ (ref. \textsuperscript{14}); we note that the ground-state behaviour of bulk $\text{Nd}_5\text{Ni}_5\text{O}_{15}$ has not yet been well established\textsuperscript{11,12}. Meanwhile, $\text{Nd}_3\text{Ni}_4\text{O}_{12}$ becomes superconducting (Fig 3b). The onset of superconductivity begins at temperatures as high as $\sim 15$ K with the point of maximum curvature at $\sim 13$ K. The resistivity ($\rho$) reaches half the normal state value at $\sim 4.5$ K and hits zero ohms by $\sim 100$ mK, as shown in the inset. The suppression of superconductivity by a magnetic field up to 9 T in the $c$ axis perpendicular to the plane of the sample is presented in Fig. 3c (see also Supplementary Note 4 and Supplementary Fig. 9). The normal state resistivity is approximately linear with temperature immediately before approaching the superconducting transition and responds
minimally to an out-of-plane magnetic field. Due to the breadth of the transition, we use the strength of the field where the resistivity reaches 90% of the normal state value, where superconducting correlations are present, as a proxy for the upper critical field (H_{c2}). Being linear in the Ginzburg–Landau model (inset, Fig. 3c; Methods) around T_{c}, this allows us to estimate an in-plane correlation length of \xi(T=0)_{\parallel} = 4.4 \pm 0.2 \text{ nm}, which is comparable to that of the doped infinite-layer compound (\ref{1}).

Particularly noteworthy in the context of infinite-layer nickelates is the temperature dependence of the Hall coefficient (Fig. 3d). The doped infinite-layer nickelates possess Hall coefficients that, while sensitive to factors such as doping levels\(^\text{23,24,27}\), thickness\(^\text{22}\) and cation composition\(^\text{22,27,28}\), ultimately remain negative at all temperatures or exhibit a zero-crossing. This evinces a two-band picture with substantive electron- and hole-pocket contributions\(^\text{22,23,24,27}\). Meanwhile, both the superconducting Nd_{NiO_{6}} and non-superconducting Nd_{NiO_{6}} layered nickelates have Hall coefficients that remain positive at all temperatures, with a semiconductor-like temperature dependence reminiscent of the underdoped and optimally doped layered cuprates\(^\text{29}\). For reference, we note that the Hall coefficients of oxidized Ruddlesden–Popper thin films behave as expected (Supplementary Fig. 10): the sudden jump in the Hall coefficient (R_{H}) below ~155 K for Nd_{NiO_{6}} probably reflects a Fermi surface reconstruction due to a charge density wave instability and the abrupt loss of carriers, as has been observed in the bulk\(^\text{30}\).

With this observation, it becomes relevant to compare the predicted electronic structure of Nd_{NiO_{6}} (n=5) square-planar layered nickelates with their infinite-layer NdNiO_{3} (n=\infty) and trilayer Nd_{NiO_{3}} (n=3) counterparts (see Fig. 4). In NdNiO_{3} (d^{9} filling), much attention has been paid to its multiband character: in the paramagnetic state, in addition to the Ni-d_{x^{2}-y^{2}} bands, Nd d states also cross the Fermi level. The latter lead to the appearance of electron pockets at the \Gamma and A points, which display mainly Nd-d_{x^{2}-y^{2}} and Nd-d_{z^{2}} character, respectively. These electron pockets give rise to self-doping of the large hole-like Ni-d_{x^{2}-y^{2}} Fermi surface\(^\text{30,31}\).

Notably, the electronic structure is three-dimensional-like, with a large \text{c} axis dispersion. In contrast, in Nd_{NiO_{6}} (at d^{9} filling), a single band per nickel crosses the Fermi level and there is no Nd d involvement; this leads to a much more cuprate-like scenario\(^\text{32}\). The electronic structure of Nd_{NiO_{6}} seems to interpolate between these

Fig. 2 | Structural characterization of the layered nickelates. a, b. High-angle annular dark-field (left) and annular bright-field (right) STEM images of the Nd_{NiO_{6}} (a) and Nd_{NiO_{6}} (b) compounds. Nd, Ni and O are represented by turquoise, red and yellow dots, respectively. Scale bars, 5 Å. c. EELS map of the Nd_{NiO_{6}} compound near the substrate–film interface. Scale bar, 5 Å. d. X-ray diffraction spectra of the n = 3 and n = 5 compounds over the full scan range (left). Substrate peaks are labelled with asterisks and curves are vertically offset for clarity. A zoomed-in region (right) illustrates how the main superlattice peaks ((0014) for n = 3 and (0022) for n = 5) shift upon reduction, as indicated by the grey arrows.
two situations: a single $d_{xy}$ band per nickel crosses the Fermi level but Nd 5$d$ bands start playing a role, even though the electron pockets related to Nd 5$d$ states are substantially smaller than those in the infinite-layer material\(^\text{13}\). These features of the electronic structure suggest that Nd–Ni 5$d$–3$d$ hybridization is less important in Nd$_6$Ni$_8$O$_{12}$ than in the infinite-layer compounds. Aside from the appearance of the neodymium-derived pockets at the zone corners, the Fermi surface of Nd$_6$Ni$_8$O$_{12}$ is analogous to that of multilayer cuprates with one electron-like and four hole-like $d_{xy}$, Fermi surface sheets\(^\text{12}\). Importantly, the Fermi surface of the quintuple-layer nickelate is much more two-dimensional-like compared to the infinite-layer nickelate compound, as the presence of the fluorite blocking layer cuts the $c$ axis dispersion. From our description of the electronic structure, we calculated low-temperature Hall coefficients ($R_H$) using semi-classical Boltzmann transport theory (Supplementary Note 6). In the $T=0$ limit, we find $R_H \approx 1 \text{mm}^3\text{C}^{-1}$ and $5 \text{mm}^3\text{C}^{-1}$ for Nd$_6$Ni$_8$O$_{12}$ and Nd$_6$Ni$_8$O$_{13}$, respectively. These values are consistent with the experimental low-temperature $R_H$ presented above and suggest that, even at identical $d^{10}$ filling levels, the layered Nd$_6$Ni$_8$O$_{12}$ compound has a weaker involvement of the Nd 5$d$ bands and is more cuprate-like than its Sr-doped NdNiO$_3$ counterpart.

In the cuprates, a large $p$–$d$ hybridization is an essential ingredient in mediating high-temperature superconductivity\(^\text{14}\). A quantitative measurement of this is the charge-transfer energy, $\Delta$, which is inversely proportional to the hybridization. In the context of infinite-layer superconducting nickelates, the larger charge-transfer energy ($\Delta_{\text{INt}} \approx 4.4 \text{eV}$)\(^\text{11,12}\) compared to cuprates has been intensively analysed. From electronic structure calculations, $\Delta$ can be obtained as the difference in energy between the Ni-$d_{xy}$ and the O-$p$ on-site energies derived from maximally localized Wannier functions (Supplementary Note 6). The charge-transfer energy for Nd$_6$Ni$_8$O$_{12}$ is $\Delta_{\text{INt}} \approx 3.5 \text{eV}$, consistent with previous work\(^\text{10}\), and for Nd$_6$Ni$_8$O$_{13}$, $\Delta_{\text{INt}} \approx 4.0 \text{eV}$. These are substantially smaller values than those obtained for the infinite-layer compounds. We can qualitatively assess this calculation using XAS on our synthesized films. Spectra at the O K-edge for the Nd$_6$Ni$_8$O$_{12}$ and Nd$_6$Ni$_8$O$_{13}$ compounds each exhibit a pre-peak feature whose intensity increase with diminishing dimensionality (Supplementary Fig. 11). Since the pre-peak corresponds to excitations from the O 1$s$ states to hybridized Ni–O 2$p$–3$d$ states, comparisons of pre-peak intensities can be used as a proxy to estimate the relative size of the charge-transfer gap or transition metal–oxygen hybridization\(^\text{15}\). Meanwhile, no pre-peak has been observed in undoped infinite-layer nickelates\(^\text{15}\).

Hence, our calculations and XAS jointly suggest a slightly reduced charge-transfer energy and enhanced covalency in the layered nickelates compared to the infinite-layer compounds.

We have synthesized a quintuple-layer square-planar nickelate that demonstrates superconductivity with a $T_c \approx -13 \text{K}$. Our square-planar trilayer and quintuple-layer compounds possess similarities to the doped infinite-layer nickelates, but notably have positive Hall coefficients up to room temperature, which is indicative of a more single-band-like picture. This, in tandem with our

THEORETICAL DESCRIPTION, SUGGESTS THAT THE QUINTUPLE-LAYER Nd₅Ni₃O₁₂
COMPOUND POSSESS A ELECTRONIC STRUCTURE THAT IS QUALITATIVELY
INTERMEDIATE BETWEEN THAT OF THE CUPRATES AND INFINITE LAYER NICKELATES, AND TUNABLE BY THE DIMENSIONALITY OF THE SYSTEM. IN REVEALING
SUPERCONDUCTIVITY IN A NEW LAYERED NICKELATE COMPOUND, WE UNLOCK THE RARE-EARTH NICKELATES AS A FAMILY OF SUPERCONDUCTORS BEYOND THE DOPED INFINITE LAYER COMPOUND. WHILE THE NICKELATES ARE THEIR OWN CLASS OF SUPERCONDUCTORS DISTINCT FROM THE CUPRATES, THEY ARE CURRIGATING THAT THE CUPRATE-MOTIVATED PREDICTIONS OF OPTIMAL dₓ²-y² FILLING HAVE YIELDED SUPERCONDUCTIVITY, WHETHER ACHIEVED THROUGH CHEMICAL DOPING OR LAYERING DIMENSIONALITY. OUR WORK OPENS UP FUTURE Avenues IN WHICH CHEMICAL DOPING AND ARTIFICIAL LAYERING MAY BE HARNESSSED IN CONCERT TO MAP OUT AND OPTIMIZE SUPERCONDUCTIVITY. IN THIS VEIN, WE SUGGEST THAT EXPLORING THE PHASE DIAGRAM AROUND OPTIMAL dₓ²-y² FILLING BY USING Sr²⁺ OR Ce⁴⁺ TO CHEMICALLY DOPED A LAYERED NICKELATE MAY BE AN EXCITING ROUTE TO FURTHER EXPAND THE FAMILY OF NICKELATE SUPERCONDUCTORS.

Methods

Synthesis of layered nickelate thin films. The elemental fluxes from the effusion cells were first estimated by synthesizing thin films of NiO on MgO and NdO$_3$ on yttria-stabilized zirconia. The thickness of these films was extracted from X-ray reflectivity patterns. These deposition rates were also verified using Rutherford backscattering spectrometry. Using these flux estimates, we then synthesized NdNiO$_3$ on LaAlO$_3$, to refine the stoichiometry. X-ray reflectivity confirms the optimized NdNiO$_3$ films were used to determine the overall monolayer dosage. Using these optimized conditions, all layered Ruddlesden–Popper nickelate films were then synthesized by sequentially depositing the neodymium and nickel sources, and shutter times of the neodymium and nickel sources accordingly. Distilled ozone flow (Heeg Vacuum Engineering) was controlled with a piezo-electric leak valve to maintain total chamber pressures in excess of 1.5×10$^{-6}$ Torr to ensure the full oxidation of nickel into the 2.67+ or 2.8+ states for the Nd$_3$NiO$_5$ and Nd$_2$Ni$_2$O$_7$ compounds, respectively. Films were synthesized to contain a total of 60 Ni–O layers, ~27 nm for Nd$_3$NiO$_5$ and ~25 nm for Nd$_2$Ni$_2$O$_7$. All films were cooled in 1×10$^{-6}$ Torr of distilled ozone to discourage the formation of oxygen vacancies.

None of the films were deposited with capping layers as has been performed elsewhere [28]. We note that the successful synthesis of the Nd$_3$NiO$_5$ yielding superconducting films is the most sensitive aspect of this experiment, and provide additional details in Supplementary Note 2.

The oxidized Ruddlesden–Popper films were then reduced into the layered square-planar phase using topotactic CaH$_2$ methods similar to those described elsewhere [16]. The as-synthesized films were cut into ~2.5 mm pieces; gently wrapped in aluminium foil suitable for ultra-high vacuum (All-foil) and inserted into borosilicate tubes (Chemglass Life Sciences), pre-baked at 200 °C, with 100 mg of CaH$_2$ pellets (99%, Alfa Aesar). The glass tubes were sealed while being pumped with a small turbomolecular pump down to <0.5 mTorr. Reductions were conducted in a convection oven (Heratherm, Thermo Fisher Scientific) at 260–300 °C for 3–6 hours, with heating rates of 10 °C/min. After reduction, the films were briefly annealed in 2-butane and isopropanol to remove CaH$_2$ residue. Additional details on the synthesis can be found in Supplementary Note 2.

Structural characterization. X-ray diffraction was performed with a Malvern Panalytical Empyrean diffractometer using Cu Kα1 radiation. Reciprocal space maps (Supplementary Fig. 3) were taken using a two-dimensional pixel detector (PIXcel3D). Cross-sectional TEM specimens were prepared using a Thermo Fisher Scientific Helios G4 UX and/or an FEI Helios 660 focused ion beam (FIB) with a final thinning step at 2 keV. HAADF- and ABF-STEM was performed using an aberration-corrected Thermo Fisher Scientific Spectra 300 X-FEG operated at 300 kV with a probe convergence semi-angle of 30 mrad. EELS measurements were carried out at 120 kV on the same instrument equipped with a Gatan Continuum spectrometer and camera. Any cleaning procedures of the FIB lamellas involving oxygen plasma were foregone for the reduced square-planar samples to prevent reoxidation into the Ruddlesden–Popper phase. Additional details may be found in Supplementary Note 3.

Transport measurements. Devices in Hall bar geometries were patterned using type II UV photoresistography processes. Devices were written on 4 inch fused silica mask plates using a Heidelberg DWL-2000 mask maker with a 4-mm write head. The photolithography for the ion milling and deposition patterns was done using a conventional SPR 220-based process. All samples were ion-milled using an Ionvac Nanoint Q2 Ar ion mill at a working temperature of 15°C (to prevent sample reoxidation) and an incident beam angle of 10°. The Ti(10)/Pt(100) (units in nm) metal contact layer was deposited on top of a deposition lithography mask via pulsed laser deposition for a standard metal lift-off process. In some cases, Cr(5)/Au(100) (units in nm) metal contact layers were deposited with an electron-beam evaporator and Hall bar channels defined by a diamondscribe. Transport measurements down to 1.8 K were conducted in a Quantum Design Physical Property Measurement System equipped with a 9-T magnet using standard a.c. lock-in techniques at ~15 Hz. Below 1.8 K, measurements were performed in a Leiden Cryogenics CF-700 dilution refrigerator down to ~50 mK. To avoid capacitive losses from high excitation a.c. frequencies which are exacerbated at low temperatures, resistances below 1.8 K were extracted from current–voltage I–V sweeps performed using d.c. techniques. A total of 4–5 I–V sweeps at each point were averaged to improve the d.c. signal-to-noise and resistances were taken from the slope fitted across ±0.5 µA. Hall coefficients were calculated using field sweeps up to 9 T; a representative example is shown in Supplementary Fig. 10.

XAS. XAS was performed at 78 K in the total electron yield at Beamlines 4.0.2 and 6.3.1 at the Advanced Light Source at Lawrence Berkeley National Laboratory. All spectra were processed and normalized to the signal impinging on a copper mesh. The spectra are further scaled at the pre-edge and normalized across the entire edge to compare relative intensities. Each spectrum presented in Supplementary Fig. 11 represents the average of 8–12 individual scans.

Computational methods. To calculate the paramagnetic electronic structure of the n = 3 and n = 5 layered nickelates, we employed density functional theory calculations using the projector augmented wave method, as implemented in the Vienna ab initio simulation package (VASP). We used a pseudopotential that treats the Nd 3f electrons as core electrons. The in-plane lattice parameters were set to match the NdGaO$_3$ substrate, and the out-of-plane lattice parameter was optimized. We find that our optimizations agree well with the experimentally measured lattice parameters (see Supplementary Note 6 for more details as well as for the calculations of the Hall coefficients).

To study the dominant pairing instability for the n = 5 compound, we solved an effective t−J model for the five NiO$_2$ layers using a slave-boson representation and generalizing the spin symmetry of the model to Sp(N) for large N to obtain the superconducting gap order parameter as a function of filling. We decoupled the exchange interactions in both Hartree and pairing channels, and obtained saddle-point solutions as functions of the total nickel doping. A detailed description of the t−J model and its corresponding solutions is presented in Supplementary Note 7.

Data availability

The data supporting the findings of this study are available from the corresponding authors upon reasonable request. Source data for Figs. 2–4 are provided with this paper.

Acknowledgements

We thank M. R. Norman and M. Mitra for discussions. We also thank K. Lee and H. Y. Hwang for discussions and technical guidance in reduction experiments; D. Erdosy, J. Lee, N. Pappas, S. Thapa and M. Wenny for continued support in reductions; H. Hijazi at the Rutgers University Laboratory of Surface Modification for assistance in Rutherford backscattering spectrometry; and J. MacArthur for electronics support. This research was funded in part by the Gordon and Betty Moore Foundations EPiQS Initiative, grant no. GBMF6760 to J. A. Mundy. Materials growth and electron microscopy were supported in part by the Platform for the Accelerated Realization, Analysis, and Discovery of Interface Materials (PARADIM) under NSF Cooperative Agreement no. DMR-2039380. Electron microscopy made use of the Cornell Center for Materials Research (CCMR) Shared Facilities, which are supported through the NSF MRSEC Program (no. DMR-1719875). The Thermo Fisher Spectra 300 X-CFEG was acquired with support from PARADIM, an NSF MIP (DMR-2039380) and Cornell University. Nanofabrication work was performed in part at Harvard University’s Center for Nanoscale Systems (CNS), a member of the National Nanotechnology Coordinated Infrastructure Network (NNCI), supported by the National Science Foundation under NSF grant no. 1541959, and in part at the University of Michigan Nanofabrication Facility. This research used resources of the Advanced Light Source, a US DOE Office of Science User Facility under contract no. DE-AC02-05CH11231. G. A. P. acknowledges support from the Paul & Daisy Soros Fellowship for New Americans and from the NSF Graduate Research Fellowship Program no. DGE-1745303. G. A. P. and D. F. S. acknowledge support from the Department of Energy, Office of Basic Energy Sciences, Division of Materials Sciences and Engineering, under award no. DE-SC0021925. Q. S., S. D. and D. C. C. were supported by the STC Center for Integrated Quantum Materials, NSF grant no. DMR-1233139. B. H. G. and L. F. K. characterized the samples with scanning transmission electron microscopy. H. L. and A. S. B. performed density functional theory calculations using the projector augmented wave method, as implemented in the Vienna ab initio simulation package (VASP). We used a pseudopotential that treats the Nd 3f electrons as core electrons. The in-plane lattice parameters were set to match the NdGaO$_3$ substrate, and the out-of-plane lattice parameter was optimized. We find that our optimizations agree well with the experimentally measured lattice parameters (see Supplementary Note 6 for more details as well as for the calculations of the Hall coefficients).

Author contributions

G. A. P., Q. S., C. M. B. and J. A. Mundy synthesized the thin films with assistance from H. P. G. A. F. and S. D. conducted the reductions with guidance from J. A. Mason. B. H. G. and L. F. K. characterized the samples with scanning transmission electron microscopy. G. A. P., A. T. P. and A. Y. performed transport measurements using fabrication assistance from S. N. and J. T. H. G. A. P., Q. S., D. C. C., A. T. N. and P. S. performed X-ray absorption spectroscopy. H. L. and A. S. B. performed density functional theory calculations. E. M. N., O. E. and A. S. B. constructed the t−J model. A. S. B. and J. A. Mundy conceived and guided the study. A. S. B. and J. A. Mundy wrote the manuscript with discussion and contributions from all authors.
