TRYANOPLASMA ATRARIA SP. N. (KINETOPLASTIDA: BODONIDAE) IN FISHES FROM THE SEVIER RIVER DRAINAGE, UTAH

J. Stephen Crammy and Richard A. Heckmann

ABSTRACT.—A total of 181 fishes belonging to 10 species were captured near Richfield, Utah, and examined for parasites. A new species of homoflagellate, Trypanoplasma atraria sp. n., was observed in 3 species: Utah chub (Gila atraria [Girard]), redside shiner (Richardsonius balteatus [Richardson]), and speckled dace (Rhinichthys osculus [Girard]). Seven other species of fishes examined in the study area were negative for T. atraria sp. n. The salmonid leech, Piscicola salmositica (Meyer), collected in the same area harbored developmental stages of Trypanoplasma, suggesting a possible leech vector for the homoflagellate. Characteristics of Trypanoplasma atraria sp. n. place it near T. salmositica, but the new species is twice as large.

Key words: Trypanoplasma atraria n. sp., blood parasites, Gila atraria, fish parasites.

Trypanoplasma is a biflagellated protozoan found in the blood of freshwater fishes in the United States. It has caused significant mortality in rainbow trout (Oncorhynchus mykiss [Walbaum]) and king salmon (O. tshawytscha [Walbaum]) under hatchery conditions (Becker and Katz 1966, Wales and Wolf 1995). This genus has also been described from the blood of marine fish (Strout 1965). Another name for the blood biflagellate of salmonids described above is Cryptobia. There are differing opinions on the use of the two genera, Cryptobia and Trypanoplasma, but these differences have been recently clarified by Lom and Dykova (1992). The genus Cryptobia was first proposed by Leidy (1846) for biflagellated protozoans occurring as parasites in the seminal vesicles of snails. Chalachnikow (1888) was the first to record the parasite in the blood of fishes, observing it in freshwater loaches in Russia. Laveran and Mesnil (1901) established the genus Trypanoplasma for a biflagellate blood parasite from freshwater fishes in France. In 1909, Crawley stated that Cryptobia from snails and Trypanoplasma from fishes were morphologically identical, and that Cryptobia had taxonomic priority. In defending the creation of the genus Trypanoplasma, Laveran and Mesnil (1912) argued that morphological similarities were not sufficient criteria for maintaining a single genus when strong biological differences, such as method of infection, were evident. The parasites in snails were transferred directly during copulation, while a leech vector was necessary to transfer the flagellate from the blood of one fish to another. Putz (1970) submitted that comparative biological studies between similar morphological types are necessary for a correct taxonomic classification. Use of the genus Cryptobia has, in most cases, emerged as the popular choice, and Trypanoplasma is generally recognized as a synonym. Recently, Lom and Dykova (1992) used Trypanoplasma for biflagellated blood-inhibiting parasites of fishes in which a leech vector is involved. Thus, we adopted the classification scheme used by Lom and Dykova (1992).

Four species of Trypanoplasma from the blood of freshwater fishes have been reported in North America. Mavor (1915) found T. borreli in a moribund white sucker (Catostomus commersoni [Lacepede]) from Lake Huron. The identification of T. borreli was based on similarities with the species initially described by Laveran and Mesnil (1901). Katz (1951) recorded C. (=Trypanoplasma) salmositica from silver salmon (O. kisutch [Walbaum]) and C. (=Trypanoplasma) lynchii from cottids in the state of Washington. Subsequent transmission studies showed C. lynchii to be a synonym of C. salmositica (Becker and Katz 1965a). Laird (1961) described C. (=Trypanoplasma) gurneyorum from northern pike (Esox lucius [Linnaeus]) and from 2 salmonids: lake whitefish (Coregonus clupeaformis [Mitchill]) and lake trout (Salvelinus namaycush [Walbaum]).

Another species, C. (=Trypanoplasma) cataractae, was described by Putz (1972a) from several cyprinids in West Virginia. This record also included the first comprehensive study of a Cryptobia (=Trypanoplasma) species that encompassed comparative morphology, mode of transmission, natural and experimental hosts, in vire and in vitro culture, histopathology, and cryopreservation. These criteria and extensive comparison with T. salmositica from the West Coast were used to justify designation of T. cataractae as a valid species.

An ectoparasitic relationship of Trypanoplasma on goldfish (Carassius auratus [Linnaeus]) maintained in aquaria was recorded by Swezy (1919). Wenrich (1931) also observed the presence of external flagellates on the gills of carp (Cyprinus carpio [Linnaeus]) in Pennsylvania. The use of the scientific name Trypanoplasma is accurate for these observations (Lom and Dykova 1992). Khan and Noble (1972) and Khan (1991) recently reported on another species of Cryptobia, C. dahli.

Involvement of a vector in transmission of Cryptobia (=Trypanoplasma) was postulated by Mavor (1915). Katz (1951) observed developmental stages of Cryptobia from the gut of the leech Piscicola salmositica and indicated it as a vector for C. salmositica. Subsequent experiments showed conclusively that the leech functioned as a vector in the transfer of C. salmositica from fish to fish (Becker and Katz.
TABLE 1. Prevalence (%) of Trypanoplasma sp. in fish examined from the main Sevier River, northern spring ponds, and southern spring ponds east of Richfield, Utah.

| Area                  | Fish species         | Number examined | Positive infections | Percent positive |
|-----------------------|----------------------|-----------------|---------------------|------------------|
| Main Sevier River     | Gila copi            | 10              | 0                   | —                |
|                       | Gila atraria         | 2               | 0                   | —                |

|                       | Salmo trutta         | 2               | 0                   | —                |
|                       | Ameiurus melas       | 2               | 0                   | —                |
|                       | Cottus bairdi        | 1               | 0                   | —                |

1965a, 1965c, Burreson 1982). Putz (1972b) showed a leech, Cystobranchus virginicus, to be a vector for T. cataractae.

Organisms of the genus Cryptobia and Trypanoplasma have been reported as parasites in marine and freshwater fishes, salamanders, frogs, heteropods, planarians, siphonophores, chaetognaths, leeches, mole crickets, lizards, snails, and also as free-living forms (Noble 1968).

Woo and Wehnert (1983) and Bower and Margolis (1983) reported that Trypanoplasma and Cryptobia of many species of fish can be acquired directly via water and not only by leeches. Bower and Margolis (1984) and Woo (1987) also considered Trypanoplasma a synonym of Cryptobia, a view not helped by Becker and Katz (1966) or Lom (1979) prior to this time.

The species of Trypanoplasma described in this article was first observed by McDaniel in 1970 (personal communication) from Utah chub (Gila atraria) near Richfield, Utah. At that time it was considered a species of Cryptobia.

Materials and Methods

Study Area

The primary collection site, located approximately 5 km east of Richfield, Utah, was subdivided into 3 major areas (Fig. 1): the main Sevier River (area 1), northern spring ponds (area 2), and southern spring ponds (area 3). The ponds are located east of the Sevier River at the base of Bull Claim Hill. The springs are rocky and contain dense stands of watercress and other aquatic plants. The river is heavily silted and almost dry during the summer. Fish were also examined from source waters of a fish hatchery in the northern spring area and from 7 stations on the Sevier River south of the principal study area to determine the local range of the hemoflagellate.

Collection and Examination of Fish

A total of 181 fish representing 5 families and 10 species were collected and examined for blood flagellates (Trypanoplasma and Cryptobia) using the “kidney strike” technique.
TABLE 2. Natural hosts, vectors, and references of *Trypanoplasma* spp. from freshwater fishes of North America.

| *T. gureneyorum*                | None given                  | *Coregonus clupeaformis*, *Salvelinus namaycush*, *Esoc lucius* | Laird 1961                  |
| *T. borrelli*                   | None given                  | *Catostomus commersoni*                                   | Mavor 1915                  |

(Putz 1970). Hemoflagellates were detected by characteristic whiplike motions of the flagella. Examination of stained preparations at higher magnification confirmed infections and permitted morphological studies.

Collection and Identification of Leeches

Ectoparasitic leeches of fishes were collected from the underside of rocks in the 2 spring areas and identified using Hoffman (1967). Specimens were confirmed by Dr. Roy W. Sawyer, Biology Department, College of Charleston, South Carolina. Leeches were maintained in the laboratory at 4°C in covered paper cups, where they could be kept in good condition for up to 3 mm.

Mounting and Staining

Blood was obtained from the caudal peduncle of infected fishes. Samples of hematopoietic tissue were also taken directly from the kidney ("kidney strike"). A thin smear was prepared on a glass slide, air-dried, fixed with methyl alcohol (100%), and stained with Giemsa (Humason 1967).

Stained smears from leeches were prepared by mortaring each leech in a small amount of Hank's balanced salt solution (Hoffman 1967). A smear from the solution was stained following the fish blood procedure. Living *Trypanoplasma* were observed in wet mounts from infected fish and mortared leeches to determine behavioral characteristics.

Morphometrics

Stained slides were examined at a magnification of 1000X. Measurements were recorded for anterior and posterior flagella lengths, body length and width, kinetoplast length, and width of the nucleus. Fifty organisms were measured and averages compared with existing measurements of other described species of *Cryptobia* and *Trypanoplasma*.

RESULTS

Natural Hosts

Examination of 181 fish at 15 stations revealed *Trypanoplasma* in Utah chub (*Gila atraria*), redside shiner (*Richardsonius balteatus*), and speckled dace (*Rhinichthys osculus*). Seven species (Table 1) appeared to be negative for the blood flagellate: Utah sucker (*Catostomus ardens* [Jordan and Gilbert]), black bullhead (*Amiaurus melas* [Rafinesque]), rainbow trout (*Oncorhynexus mykiss*), brown trout (*Salmo trutta* [Linnaeus]), carp (*Cyprinus*...
capio), leatherside chub (*Gila copei* [Jordan and Gilbert]), and mottled sculpin (*Cottus bairdi* [Girard]). Rainbow trout, carp, and Utah sucker all came from the northern springs ponds (area 2), while the leatherside chub, brown trout, and mottled sculpin were only in the Sevier River. Utah chub and speckled dace were abundant in the springs, but only 2 chub and 1 speckled dace were collected from the Sevier River. The 2 black bullhead were from the southern spring ponds (area 3). Only redside shiner was abundant at all collection sites. Reported natural hosts and vectors of described species of *Trypanoplasma* and *Cryptobia* from North America are given in Table 2.

**Prevalence of Trypanoplasma**

in the Richfield, Utah, Area

Fish infected with *Trypanoplasma* were, with 1 exception, obtained in the 2 spring areas along Bull Claim Hill (Table 1). One speckled dace was collected where 1 of the northern springs emptied into the Sevier River. In area 1, all individuals of the 3 host species were infected.

---

Fig. 2. *Trypanoplasma atraria* sp. n. from fishes (a) and a leech vector (b, c, d): 1, anterior flagellum; 2, blepharoplast; 3, kinetoplast; 4, nucleus; 5, posterior flagellum. (b) Both flagella in anterior position, (c) posterior migration of flagellum, (d) common stage in leech with short posterior flagellum.
At area 2, the parasite was present in 30% of Utah chub and absent in speckled dace and redside shiner (Table 1). Microscopic examination of kidney fluids from northern spring fishes revealed 3–4 flagellates per field at 100X. For the southern springs, examination of several fields at the same magnification was necessary to locate a single parasite, indicating a much lower level of infection in that area.

Vector

The parasitic leech recovered in the study area was identified as *Piscicola salmositica*, a common ectoparasite of fish in freshwater streams of the West Coast of the United States (Hoffman 1967). Microscopic examination of the mortared leech preparation revealed several developmental stages of *Trypanoplasma*, which were all morphologically different from the parasite stage in the fish (Fig. 2). This correlates with observations by other workers in the field (Lom and Dykova 1992).

*Piscicola salmositica* was observed from the northern springs ponds and the northernmost portion of the southern area. Extensive search of the remainder of the southern springs and Sevier River produced no additional specimens of the leech. Leech prevalence was high in autumn and continued until peak numbers were observed in the middle of February. By late March to July, only a small number of leeches were observed.

Rainbow trout, carp, Utah sucker, and Utah chub were hosts for *P. salmositica*. Leeches were never observed on redside shiner or speckled dace.

Description of *Trypanoplasma atraria* sp. n.

(Fig. 3)

Average parameters given in micrometers with ranges in parentheses of 50 stained specimens of *Trypanoplasma atraria* sp. n. are as follows: body length 30.5 (27.36), body width 4.5 (3–7), length of anterior flagellum 29.2 (23–34), length of posterior flagellum 20.9 (15–24), nuclear width 2.7 (2–3.5), kinetoplast length 5.9 (4.5–7). Type specimens including paratypes have been deposited (USNM Helminthological Collection Nos. 74436 and 74437), with additional paratypes in the junior author’s collections. Morphometric comparisons with other described species of *Trypanoplasma* from North America are shown in Table 3.

*Trypanoplasma atraria* sp. n. under phase microscopy revealed a high degree of polymorphism and constant whiplike undulatory movement. Stages in the leech exhibited a quivering motion with much less distortion of body shape. The most common stage visible in the leech had a short posterior flagellum and was less than 1/2 the overall size of that observed from the fish host (Fig. 2d).

**DISCUSSION**

Published host records for *Trypanoplasma* in North America include 25 species of freshwater fishes (Putz 1972a). *Trypanoplasma salmositica* is reported to parasitize 19 species, *T. cataractae* 4, *T. gurneyorum* 3, and *T. borreli* only a single host species. Results of this study showed *T. atraria* in 3 cyprinids: Utah chub, redside shiner, and speckled dace.

The only known vectors of *Trypanoplasma* are parasitic leeches. Two species have been demonstrated as vectors in North America: *Piscicola salmositica* as a vector of *T. salmositica* (see Becker and Katz 1965a) and
Cystobranchus virginiticus as the vector of T. cataractae (see Putz 1972a). The salmonid leech, Piscicola salmositica, is probably the hemoflagellate vector in this study. No direct transmission experiments were conducted, but leeches were observed parasitizing fishes at the collection sites, and Trypanoplasma was observed in leech guts. The protozoan appears to undergo developmental changes within the leech with the trailing flagellum migrating anterior to posterior and forming the undulating membrane (Fig. 2). The size of the flagellate in the leech was about 1/3 to 1/2 that of the parasite in the fish host. Becker and Katz (165a) reported P. salmositica as endemic to the Pacific Coast of North America. Cope (1958) and Heckmann (1971) identified salmonid leeches from cutthroat trout in Yellowstone Lake. Direct transmission studies would clarify the role of the leech relative to fish infections with T. atraria.
