Rab17 mediates differential antigen sorting following efferocytosis and phagocytosis

Charles Yin¹, Yohan Kim¹, Dean Argintaru¹ and Bryan Heit*¹

Macrophages engulf and destroy pathogens (phagocytosis) and apoptotic cells (efferocytosis), and can subsequently initiate adaptive immune responses by presenting antigens derived from engulfed materials. Both phagocytosis and efferocytosis share a common degradative pathway in which the target is engulfed into a membrane-bound vesicle, respectively, termed the phagosome and efferosome, where they are degraded by sequential fusion with endosomes and lysosomes. Despite this shared maturation pathway, macrophages are immunogenic following phagocytosis but not efferocytosis, indicating that differential processing or trafficking of antigens must occur. Mass spectrometry and immunofluorescence microscopy of efferosomes and phagosomes in macrophages demonstrated that efferosomes lacked the proteins required for antigen presentation and instead recruited the recycling regulator Rab17. As a result, degraded materials from efferosomes bypassed the MHC class II loading compartment via the recycling endosome – a process not observed in phagosomes. Combined, these results indicate that macrophages prevent presentation of apoptotic cell-derived antigens by preferentially trafficking efferocytosed, but not phagocytosed, materials away from the MHC class II loading compartment via the recycling endosome pathway.

Cell Death and Disease (2016) 7, e2529; doi:10.1038/cddis.2016.431; published online 22 December 2016

Clearance of apoptotic cells in a timely and efficient manner is essential for preventing the induction of inflammation and the maintenance of homeostasis.¹ ¹² The process of apoptotic cell clearance, termed efferocytosis, is performed by both professional phagocytes such as macrophages³ ⁴ and dendritic cells,⁵ ⁶ and by some non-phagocytic cell types such as epithelial cells.⁷ ⁸ Apoptotic cells that are not cleared undergo secondary necrosis, driving inflammation and autoimmunity through the release of self-antigens and proinflammatory intracellular contents into the extracellular milieu.⁹ Efferocytosis is a particularly important physiological function of macrophages, with defective macrophage efferocytosis implicated in the development of a number autoimmune and inflammatory disorders including systemic lupus erythematosus¹⁰ ¹² and atherosclerosis.⁵ ¹³ ¹⁶ Despite recognition of the importance of efferocytosis in the maintenance of homeostasis, the mechanisms regulating efferocytosis remain poorly elucidated. It is thought that the molecular mechanisms of efferocytosis resembles those of phagocytosis, with the important distinction that the ultimate outcome of phagocytosis is the induction of inflammation and antigen presentation, whereas efferocytosis is immunologically silent.² ¹⁰ ¹⁷ While a number of ligands, mediators and receptors that regulate efferocytosis have been identified and characterized,¹⁰ little is known of the maturation process that degrades efferocytosed cells, or the processes that determine the ultimate fate of degraded apoptotic cells.

In phagocytosis, the phagosome maturation process responsible for the degradation of engulfed bacteria is well characterized (reviewed in Flannagan et al.¹⁸), and the maturation of efferosomes appears to share much of the same cellular machinery.¹⁹ In both processes the target microbe or apoptotic cell is internalized into a plasma membrane-derived vacuole, respectively, termed the phagosome and efferosome, where these engulfed targets are degraded. The earliest maturation event following the internalization of phagocytic and efferocytic cargos is the recruitment of the small GTPase Rab5 to the nascent phagosome or efferosome, a process driven by the Rab5 GTPase-activating protein G apex-5.²⁰ Once activated, Rab5 mediates the fusion of early endosomes to the phagosome or efferosome via the Rab5 effectors EEA-1, Vps-34 and Mon1a/b.¹⁹ ²¹ ²² Within minutes of engulfment Rab5 is exchanged for Rab7, upon which Rab7 then mediates the fusion of late endosomes and lysosomes with the phagosome or efferosome. While this latter portion of the efferocytosis pathway has not been fully characterized, it is believed to proceed in a manner identical to that of phagocytosis. In phagocytosis, inactive GDP-bound Rab7 is exchanged for Rab5 by a complex of Mon1a/b and Ccz-1, and is then activated by the exchange of GDP for GTP; a process induced by either Ccz-1 or the HOPS complex.²¹ ²³ Active Rab7, through effectors such as RILP and ORPL1, coordinates the movement of lysosomes along microtubules and their subsequent fusion with the phagosome, thereby delivering the vacuolar ATPase and catabolic enzymes that mediate the degradation of phagocytosed materials.²⁴ ²⁶ Ultimately, the phagolysosome containing this degraded phagocytosed material matures into a tubular lysosome in which the loading of MHC class II with phagocytosed antigens occurs.²⁷

The consequence of phagosome maturation is the induction of both inflammatory signaling and antigen presentation by the phagocyte.

In contrast, efferosome maturation is known to be anti-inflammatory and non-immunogenic. Immediately following the efferocytic uptake of apoptotic cells, PPPα and the atypical chemokine receptor D6 initiate signaling, which suppresses early inflammatory processes such as the oxidative burst.

This suppression of inflammation is maintained over intermediary periods of time through transcriptional processes initiated by these receptors. The upregulation of miR-21 following efferocytosis inhibits inflammatory signaling by silencing PDCD4 and PI3K, resulting in decreased TNFα expression through p38 MAPK-dependent signaling, while simultaneously enhancing IL-10 production and further uptake of apoptotic cells through increased PI3K/AP-1 signaling.

In addition to inducing miR-21, continued signaling through PPPα directly drives the expression of anti-inflammatory cytokines including IL-10 and TGFβ. This anti-inflammatory state can be maintained over prolonged periods of time through the polarization of macrophages to an anti-inflammatory/pro-efferocytic M2 or M2c state.

While these processes contribute to creating an anti-inflammatory environment, it remains unclear how immunogenicity is avoided following efferocytosis. Tissue-resident macrophages constitutively express MHC class II and costimulatory molecules, as do in vitro unpolarized (M0) and M2-polarized macrophages. Indeed, M2 macrophages are fully competent to present antigens, and can induce naive CD4+ T cells to differentiate into Th17 effectors. Clearly, additional mechanisms must be in place to prevent the immunogenic presentation of apoptotic cell-derived antigens. In this study, we tested the hypothesis that efferocytosed apoptotic cells undergo a novel maturation process that bypasses the MHC class II loading compartment. Using mass spectrometry and fluorescence microscopy, we identified a Rab17-dependent maturation process that mediates the transfer of degraded apoptotic cell materials to the recycling endosome and away from the MHC class II loading compartment, thereby preventing apoptotic cell-derived materials from intersecting the macrophage antigen presentation machinery.

**Results**

**Efferosomes and phagosomes share a common early maturation pathway.** Phagocytic cargos are degraded by a well-characterized maturation pathway in which the sequential acquisition of Rab5 and Rab7 mediates the sequential fusion of early endosomes, late endosomes and lysosomes with the phagosome. Evidence from Caenorhabditis elegans and mammalian cell lines indicate that this same maturation pathway degrades efferocytosed apoptotic cells.

However, these studies did not use professional antigen-presenting cells (pAPC), which may use an alternative pathway to avoid antigen presentation following uptake of apoptotic cells. To test whether apoptotic cells were trafficked through a novel maturation pathway in pAPCs, we tracked the recruitment of ectopically expressed Rab5-GFP and Rab7-RFP in J774.2 macrophages engaged in phagocytosis (Figures 1a and c) or efferocytosis (Figures 1b and d) of 5 μm diameter synthetic phagocytic or efferocytic targets. Both efferosomes and phagosomes sequentially recruited Rab5 and Rab7, with efferosomes transitioning from a Rab5-positive to Rab7-positive compartment with slightly slower temporal dynamics than phagosomes (Figures 1c and d). To confirm that both phagosomes and efferosomes were completing maturation, we immunostained human PBMC-derived M0 macrophages for the lysosomal marker LAMP1 40 min after engulfment of synthetic phagocytic or efferocytic targets (Figure 1e).

Significant LAMP1 accumulation was observed on phagosomes and efferosomes, confirming that vacuoles containing both types of cargo fuse with lysosomes.

Last, we assessed the possibility that macrophage polarization may result in the selective uptake of phagocytic versus efferocytic targets (Figure 1f). M0 and M2 macrophages were highly efferocytic, while M1 macrophages and primary human dendritic cells were poorly efferocytic. Furthermore, no selectivity was observed for phagocytic targets, indicating that any capacity to differentially present efferosomal versus phagosomal antigens must occur following both target engulfment and the canonical Rab5/Rab7-mediated maturation pathway.

**Mass spectrometric identification of late regulators of efferosome and phagosome maturation.** Given that efferosomes and phagosomes shared the same early maturation pathway, any selective processing of these targets likely occurs at a later time point. As such, we recovered efferosomes and phagosomes using 3 μm diameter magnetic bead mimics of efferocytic and phagocytic targets from M0-polarized human macrophages, 40 min after initiation of efferocytosis or phagocytosis. Proteins from the recovered efferosomes and phagosomes were resolved using SDS-PAGE, revealing a number of proteins selectively recruited to efferosomes versus phagosomes (Supplementary Figure 1). These unique proteins were subsequently excised and identified by liquid-chromatography/mass spectrometry. Phagosomes (Table 1) contained many of the proteins expected of a vesicle maturing into an MHC class II loading compartment, notably MHC class II and indicators of Golgi-to-lysosome trafficking (Rab6b, PIK4). In addition, phagosomes were enriched in a number of proteins involved in GTPase and kinase signaling. In marked contrast, efferosomes (Table 2) lacked MHC class II and the markers of Golgi-to-lysosome trafficking observed on phagosomes. Efferosomes instead recruited proteins that mediate vesicular trafficking, cytoskeletal organization and ubiquitination/ISG15ylation (Table 2). Of particular interest were the Rab-family GTPases Rab17 and RASEF (Rab45), both of which have been implicated in trafficking to recycling endosomes and exocytosis. Combined, these results suggest that efferocytic cargos are intercepted before formation of the MHC class II loading compartment and are redirected to a recycling or exocytic cellular compartment.

**Rab17 is persistently recruited to efferosomes but not phagosomes.** To assess the role of Rab17 in phagocytosis and efferocytosis, we performed live cell microscopy of J774.2 macrophages ectopically expressing the plasma membrane marker PM-RFP and Rab17-GFP as they
engulfed beads mimicking efferocytic or phagocytic targets. As expected, both phagocytic and efferocytic targets were internalized into plasma membrane-derived vacuoles demarcated by PM-RFP (Figures 2a and b). Rab17 transiently localized to phagosomes, with dynamics similar to that of Rab5 (Figures 2a and c). In marked contrast, Rab17 was persistently recruited to efferosomes, displaying only a modest decrease in recruitment over the hour following engulfment of the efferocytic target (Figures 2b and c). Close inspection of individual efferosomes revealed that this recruitment was not constant, and rather that Rab17 is repeatedly recruited in a series of waves, suggestive of repeat sampling of efferosomes by Rab17 (Figure 2d). Rab17 expression was observed in primary human PBMC-derived M0-, M1- and M2-polarized macrophages and DCs, with late recruitment of Rab17 observed to efferosomes in M0- and M2-polarized macrophages and DCs (Supplementary Figure 2). RASEF and Rab6b, the other Rab-family GTPases identified in our mass spectrometry screen, did not significantly associate with either phagosomes or efferosomes (data not shown).

Because our model system used non-digestible mimics of bacterial and apoptotic cells, we could not assess whether Rab17 altered the trafficking of degraded materials derived

**Figure 1** Efferosomes and phagosomes share a common early maturation pathway. Fixed and live cell microscopy was used to assess the localization of Rab5, Rab7 and the lysosomal marker LAMP1 to efferosomes and phagosomes containing 5 μm diameter bead-based mimics of apoptotic cells and immunoglobulin G (IgG)-opsonized pathogens. (a and b) Recruitment of Rab5 and Rab7 to phagosomes (a) and efferosomes (b) 10, 20 and 30 min following engulfment by J774.2 macrophages. Ex. Beads indicates non-internalized (i.e. extracellular) beads. (c and d) Dynamics of Rab5 and Rab7 recruitment to phagosomes (c) and efferosomes (d). T = 0 is set as the video frame when complete sealing of the phagosome/efferosome was observed; data are normalized to maximum Rab5 or Rab7 intensity on each individual phagosome. (e) Immunostaining of LAMP1 accumulation in phagosomes or efferosomes in human peripheral blood mononuclear cell (PBMC)-derived M0 macrophages. (f) Uptake of apoptotic cell mimics (Efferosomes) and IgG-opsonized pathogen mimics (Phagosomes) by human PBMC-derived M0-, M1- and M2-polarized macrophages and DCs, expressed as the number of beads engulfed per cell. Data are representative of (a, b and e) or quantifies (c, d and f) at least 30 cells imaged across five independent experiments. Data are presented as mean or mean ± S.E.M. *P<0.05 compared with uptake of the same type of target by M0 macrophages. Scale bars are 5 μm.
from efferosomes or phagosomes. As such, we performed live cell imaging of Rab17-GFP- and PM-RFP-expressing macrophages as they engulfed *Escherichia coli* or apoptotic cells covalently labeled with a degradation-resistant, pH-stable far-red fluorophore. Bacterial phagocytosis did not differ from the mimics, with *E. coli* internalized into a compartment that transiently colocalized with Rab17 and retained PM-RFP for at least 90 min (Figures 3a, c and d). In marked contrast, macrophages efferocytosed small fragments (apoptotic bodies) from apoptotic cells into PM-RFP-demarcated efferosomes, on which Rab17 was retained for prolonged periods of time (Figures 3b, c and e). Interestingly, at later time points, degraded apoptotic cell materials were observed to move into a compartment negative for PM-RFP (Figure 3d), a phenomenon not observed with non-degradable targets (Figure 2b), suggesting that degraded efferocytosed materials were being directed out of the canonical maturation pathway—a process not observed with *E. coli* (Figure 3e), indicating that the degraded apoptotic cells and *E. coli* had been trafficked into different cellular compartments.

**Rab17 mediates the trafficking of degraded apoptotic cell materials to the recycling endosome.** The previous data are consistent with a model in which phagocytosed materials traffic through the canonical maturation pathway, whereas efferocytosed materials are redirected into another cellular compartment by Rab17. Given that Rab17 has previously been found to regulate recycling and exocytosis, it was likely that efferocytosed materials were being trafficked from the efferosome to the recycling endosome.\(^{41,42}\) We therefore assessed the recruitment of Rab17, a recycling endosome marker (transferrin receptor, TfR) and MHC class II to phagosomes and efferosomes. Consistent with the canonical maturation process, 90 min following engulfment most phagosomes had recruited MHC class II but not Rab17 or TfR (Figures 4a and b). In contrast, efferocytosed materials did not colocalize with MHC class II, which remained diffusively distributed throughout the cell (Figure 4c). Instead, efferosomes strongly colocalized with TfR, with a portion colocalizing with both Rab17 and TfR (Figure 4d). We next attempted to knockdown Rab17, but transfection with siRNA concentrations that reliably knocked down Rab17 expression also inhibited phagocytosis and efferocytosis (Figure 4e). Instead, we transfected J774.2 cells with a mCherry-tagged dominant-negative Rab17 at a dose that inhibited ~50% of efferocytosis and phagocytosis (0.5 \(\mu\)g per well; Figure 4e). Dominant-negative Rab17 was not recruited to phagosomes, and was recruited to a significantly lower fraction of efferosomes compared with wild-type Rab17 (Figure 4f and Supplementary Figure 3). Instead, expression of dominant-negative Rab17 significantly increased the association of MHC class II and decreased the association of TfR, with efferosomes (Figure 4f and Supplementary Figures 3c and d). Combined, these results indicate that Rab17 is selectively recruited to efferosomes, where it mediates the transfer of degraded apoptotic cell material into the recycling endosome.

Discussion

Macrophages are tasked with the engulfment and destruction of both apoptotic cells and pathogens, and following engulfment must, respectively, generate immunologically silent versus immunogenic responses. While several processes that enable macrophages to suppress inflammatory responses following engulfment of apoptotic cells have been reported,4–7,31–36 identification of a mechanism preventing antigen presentation following efferocytosis, but not phagocytosis, remains elusive. In this study, we have identified a Rab17-dependent pathway in which macrophages redirect degraded apoptotic cells away from the MHC class II loading compartment and towards the recycling endosome, where disruption of this pathway resulted in degraded apoptotic cell materials reaching an MHC class II-positive intracellular compartment. This mechanism appears to be present in dendritic cells, as well as macrophages, both of which are capable of presenting phagocytosed antigens on MHC class II. Although previous studies have demonstrated a need for TLR or cytokine signaling to induce the formation of an MHC class II loading compartment and loading of phagosome-derived antigens onto MHC class II,47,48 the selective recruitment of Rab17 to efferosomes and its exclusion from phagosomes occurred in the absence of these signals, suggesting that this pathway is intrinsic to efferocytic receptor signaling and independent of TLR/cytokine-induced formation of the MHC loading compartment.

Rab17 function is best understood in polarized epithelial cells where it is required for both receptor recycling through the apical recycling compartment and for receptor-mediated transcytosis.42,43 Disrupting Rab17 in polarized epithelial cells resulted in the inappropriate basolateral-to-apical transcytosis of transferrin and an accumulation of normally basolateral proteins on the apical facet of the cell.42,46 While the role of Rab17 in non-polarized cells is not completely elucidated, it is known to localize to the recycling endosome,42 and is required for the exocytic processes driving both the release of melanosomes from melanocytes and the extension of dendrites from hippocampal neurons.41,47,48 Moreover, Rab17 is required for the formation of bactericidal autophagosomes following Group A Streptococci invasion of epithelial cells.49 Our observation that Rab17 is required for the trafficking of apoptotic cell-derived materials from the phagolysosome to the recycling endosome is consistent with Rab17’s role in mediating traffic through the recycling endosome, and while it was not observed in this study, it is possible that the capacity of Rab17 to regulate exocytosis may mediate the expulsion of degraded apoptotic cell materials from the macrophage. At this time, the role of Rab17 in other immune cells has not been investigated. However, the portion of the maturation process regulated by the sequential

acquisition of Rab5 and Rab7 components has been observed to function in a nearly identical manner following phagocytosis in macrophages, DCs and neutrophils, and following efferocytosis in macrophages and DCs. Moreover, we have observed Rab17 recruitment to efferosomes late in the maturation process in murine macrophage cell lines, primary human macrophages and primary human DCs, indicating that Rab17 likely acts to prevent antigen presentation in both macrophages and dendritic cells. In addition, Rab17 expression has been reported in other efferocytic cell types, including epithelial cells. Although epithelial cells do not normally present antigens on MHC class II, the presence of Rab17 in these cells suggests that they may sort apoptotic cell-derived materials via the recycling endosome, perhaps expelling degraded apoptotic cell materials from the apical cell surface.

Rab17 is known to be recruited and activated by Rabex-5, a guanine exchange factor that can recruit and activate both Rab17 and Rab5, and indeed, this pathway likely accounts for the transient recruitment of Rab17 to phagosomes observed in this study. This initial wave of Rab17 may be involved in the rapid recycling of phagocytic and efferocytic receptors from the nascent phagosome and efferosome, a process required to maintain phagocytic and efferocytic capacity by returning receptors to the cell surface. Indeed, the initial wave of Rab17 recruitment and the deleterious effect of dominant-negative Rab17 expression on phagocytosis and efferocytosis that we observed is consistent with the

**Figure 2** Rab17 is selectively retained on efferosomes. established role of receptor recycling in phagocytosis. Previous studies have shown that Rab11-mediated recycling is required for maximal phagocytic capacity in macrophages, with the expression of dominant-negative Rab11 greatly reducing phagocytosis through FcY receptors.\textsuperscript{54} Defective Rab11 signaling resulted in the trapping of receptors in the recycling endosome, thereby impairing further activity through sequestering receptors from the cell surface.\textsuperscript{55} Rab17 is known to mediate the recycling of other membrane receptors such as the transferrin, plgR and Fc-like receptors,\textsuperscript{42,43} indicating a theoretical capacity to mediate the recycling of efferocytic and phagocytic receptors. Indeed, we did not observe any phagocytic receptors, and only weakly detected two efferocytic receptors (CD36 and Galectin-3)\textsuperscript{56,57}, in phagosomes and efferosomes recovered late in the maturation process. Furthermore, Rab17 knockdown or expression of dominant-negative Rab17 decreased both phagocytosis and efferocytosis, consistent with the need for ongoing receptor recycling to maintain phagocytic capacity.\textsuperscript{54} Combined, these data suggest that early Rab17 recruitment...
recycles receptors from the nascent phagosome or efferosome, and is required for the maintenance of phagocytic/efferocytic capacity of macrophages.

While Rabex-5 mediated recruitment may explain the initial wave of Rab17 observed on phagosomes, it is unlikely to be involved in the repeated waves of Rab17 recruitment observed.
throughout efferosome maturation. Indeed, the Rab7 adaptor Mon1 is known to displace Rabex-5 from the phagosome,\(^\text{58}\) and our results indicate that Rab17 sampling of the efferosome temporally overlaps with Rab7 recruitment to the efferosome. Another Rab GTPase, Rab27, can be localized to the phagosome,\(^\text{69}\) activate Rab17\(^\text{41}\) and drive exocytosis,\(^\text{60,61}\) indicating that it may be a candidate for the recruitment of Rab17 to the efferosome. However, we were unable to identify Rab27 on efferosomes in either our mass spectrometry screen or by immunofluorescence (data not shown), although the sensitivity and temporal limitations of these methods may have prevented identification of transient or weak Rab27 recruitment. The enrichment of ubiquitination/ISG15ylation machinery on the efferosome identified in our mass spectrometry screen may indicate a third possible mechanism for Rab17 recruitment to efferosomes. Rab17 is known to require monomoylation, a ubiquitin-like post-translational modification, for its recruitment and activity.\(^\text{60}\) The presence of molecular machinery, including E3 ligases that modify proteins with ubiquitin and ISG15 motifs, may indicate that Rab17 recruitment and activation on efferosomes may occur through a SUMO-like post-translational modification driven by efferosome-resident E3 ligases.

The sorting of apoptotic cell-derived antigens away from the MHC class II loading compartment is likely an important component of peripheral tolerance, as the 60 to 80 billion apoptotic cells generated daily in the human body represents a significant antigenic burden dealt with predominantly by resident phagocytes.\(^\text{62}\) Unsurprisingly, defects in efferocytic receptors and signaling molecules are associated with the onset of autoimmune disorders including rheumatoid arthritis,\(^\text{11,63,64}\) multiple sclerosis and systemic lupus erythematosus,\(^\text{11,63,64}\) and with chronic inflammatory conditions such as atherosclerosis.\(^\text{13,15,65}\) However, this regulation must be more nuanced than simply sorting all degraded apoptotic cells away from the MHC class II loading compartment, as apoptotic cells can harbor pathogens and act as vehicles for pathogen dissemination.\(^\text{66}\) Furthermore, MHC class II stability and trafficking to MHC class II loading compartments is enhanced following TLR or cytokine stimulation of dendritic cells, suggesting that inflammatory signaling may act to enhance trafficking and loading of MHC class II following phagocytosis.\(^\text{67,68}\) The effects of a proinflammatory micro-environment or the activation of TLR/cytokine signaling on Rab17-mediated trafficking of efferosomal contents away from the MHC class II compartment remains to be characterized.

In summary, we have delineated a Rab17-dependent pathway that allows phagocytes to selectively divert engulfed and degraded apoptotic cells away from the MHC class II loading compartment and into the recycling endosome, thereby limiting the potential for presenting autoantigens. These findings suggest that the differential sorting of apoptotic cell-derived versus pathogen-derived antigens is a hereto unappreciated mechanism involved in maintaining peripheral tolerance.

Materials and Methods

**Materials.** J774.2 macrophages, PM-RFP, Rab5-GFP, Rab7-mCherry and TIR-GFP expression constructs were gifts from Dr. Sergio Grinstein (Hospital for Sick Children, Toronto, ON, Canada). E. coli DH5\(\alpha\) and ML35 were gifts from Drs. John McCormick and Susan Koval, respectively (University of Western Ontario, London, ON, Canada). Human Rab17 cDNA was purchased from the Harvard PlasmID Repository (Boston, MA, USA). RPMI, DMEM, Trypsin-EDTA and fetal bovine serum (FBS) were purchased from Wisent (St. Bruno, QC, Canada). Recombinant human M-CSF, GM-CSF, INF\(\gamma\) and IL-4 were purchased from PeproTech (Rocky Hill, NJ, USA). No. 1.5 thickness round coverslips and 16% paraformaldehyde (PFA) were purchased from Electron Microscopy Supplies (Hatfield, PA, USA). Colloidal Coomassie Blue was purchased from Bio-Rad (Mississauga, ON, Canada). Lyophilized-poly, all fluorescent secondary antibodies and fluorescently labeled streptavidin were purchased from Cedarslane Laboratories (Burlington, ON, Canada). Anti-mouse MHC class II and Cell Proliferation Dye eFluor 670 were purchased from eBioscience (San Diego, CA, USA). Phosphatidyserine (PtdSer), phosphatidylinositol (PtdCho) and biotin-phosphatidylethanolamine (biotin-PE) were purchased from Avanti Polar Lipids (Alabaster, AL, USA). Salmonella lipopolysaccharide and human IgG were purchased from Sigma-Aldrich (St. Louis, MS, USA). Anti-human LAMP1 was purchased from the Developmental Studies Hybridoma Bank (Iowa City, IA, USA). Phusion DNA polymerase, FugeneHD, dithio-bis[succinimidyl propionate], dithio-bismaleimidoethane, Permafluor and ON-TARGETplus siRNA were purchased from Thermofisher (Mississauga, ON, Canada). DNA oligos were purchased from IDT (Corvallile, IA, USA). Restriction enzymes and T4 DNA ligase were purchased from New England Biolabs (Whitby, ON, USA). Silica and silica-functionalized magnetic beads of 3–5 µm were purchased from Bangs Laboratories (Fishers, IN, USA). Anti-Rab17 was purchased from Proteintech (Chicago, IL, USA). All other chemicals were purchased from Canada BioShop (Mississauga, ON, Canada).

**J774.2 macrophage culture.** J774.2 murine macrophages were cultured in T25 tissue culture flask containing 5 µl of DMEM buffered with sodium bicarbonate and supplemented with 10% FBS. Cells were grown to 80% confluency at 37 °C in a 5% CO\(\text{2}\) incubator and passaged by cell scraping. Cells were cultured for no more than six generations, at which time new cells were revived from liquid nitrogen stocks. For microscopy experiments, no. 1.5 thickness, 18 mm diameter round coverslips were placed into the wells of a 12-well tissue culture plate, 1 ml of DMEM +10% FBS added to each well and 0.2 ml (~2.5×10\(^5\) cells per well) of the above cell suspension added to each well. Cells were cultured for at least 8 h before transfection. Transfection with DNA vectors or siRNA was conducted using FugeneHD, as per the manufacturer’s instructions. Briefly, for each well in a 12-well plate, 1.1 µg of DNA or 0.75 µg of siRNA was diluted into 100 µl of serum-free DMEM, followed by 3.3 µl of FugeneHD. The resulting mixture was incubated for 20 min at room temperature, and then added dropwise to the J774.2 cells. Cells were incubated for at least 18 h at 37 °C in a 5% CO\(\text{2}\) before imaging.

**Human macrophage and DC culture.** The collection of blood from healthy donors was approved by the Health Science Research Ethics Board of the University of Western Ontario and venipuncture was performed in accordance with the University of Western Ontario Tri-Council Policy Statement on human research. Blood was drawn into heparinized vacuum collection tubes, layered on an equal volume of lympholyte-poly and centrifuged at 300 × g for 35 min at 20 °C. The top band of peripheral blood mononuclear cells was collected, washed once (300 × g, 6 min, 20 °C) with phosphate-buffered saline (PBS, 137 mM NaCl, 2.7 mM KCl, 10 mM Na\(_2\)HPO\(_4\), 1.8 mM KH\(_2\)PO\(_4\)), and the cell pellet was suspended in RPMI-1640+10% FBS, 20 °C supplemented with sodium bicarbonate (10 mM Na\(_2\)HPO\(_4\), 1.8 mM KH\(_2\)PO\(_4\)), and the cell pellet was suspended in RPMI-1640+10% FBS, 20 °C supplemented with sodium bicarbonate (10 mM Na\(_2\)HPO\(_4\), 1.8 mM KH\(_2\)PO\(_4\)), and then added dropwise to the J774.2 cells. Cells were incubated for at least 18 h at 37 °C in a 5% CO\(\text{2}\) before imaging.

**Preparation of synthetic phagocytic and efferocytic targets.** Synthetic targets were prepared as per our previously published methods.\(^\text{69}\) Briefly, for imaging experiments 5 µm silica beads, and for mass spectrometry experiments 3 µm silica-functionalized magnetic beads, were coated with lipids or IgG to
produce beads that mimic apoptotic cells or bacteria, respectively. Apoptotic cell membrane mimics were prepared by preparing 0.4 mmol of a lipid solution comprised of 19.8% PtdSer, 80% PtdChol and 0.2% bio-TE -15-minute centrifugation, aspiration of the supernatant and resuspension in 1 ml of PBS. Beads were suspended in 100 μl of PBS after the final wash. IgG-coated beads were then washed by incubating for 10 min at 70 °C, followed by incubation with 0.5 μM Cell Proliferation Dye eFluor 670 for 5 min at room temperature. Excess dye was quenched by the addition of 0.9 ml of fresh LB media and the cells were washed 3 x in PBS. After washing, the cells were osazonized by resuspending the bacteria in 1 ml of DMEM+10% human serum, incubating at 37 °C for 10 min, washed once in PBS and resuspended in 0.1 ml of PBS. Bacteria were used within 24 h of preparation.

Mass spectrometry. For mass spectrometry assays, 1.8 x 10^7 (~60 μl of bead mimics or ~10 μl of apoptotic cells or heat-killed E. coli). Targets were mixed into the wells by gently shaking and forced into contact with the macrophages by a 1 min, 250 × g centrifugation. For live cell microscopy experiments, cell-target mixtures were kept at 10 °C until imaged, whereas samples for fixed-cell imaging were immediately returned to a 5% CO2 incubator at 37 °C. For live cell imaging experiments, coverslips were transferred to a Leiden chamber filled with 37 °C imaging buffer (150 mM NaCl, 5 mM KCl, 1 mM MgCl2, 100 μM EGTA, 2 mM CaCl2, 20 mM HEPES, 1.5 g/l NaHCO3) and the Leiden chamber placed onto a heated CO2-perfused live cell piezolectric stage of a Leica DMi6000B microscope equipped with a x 100/1.0 NA objective, photomets Evolve-512 delta EM-CCD camera, Chroma Sedat Quad filter set and the Leica Application Suite X software platform (Leica Microsystems, Concord, ON, Canada). The positions of 5–15 transfected cells were marked using the mark and find feature, and live cell acquisitions of each marked cells acquired at 0.5–1 frames per min, with recordings conducted for 60–120 min per coverslip. For fixed-cell imaging, cells were incubated at 37 °C/5% CO2 for the desired time following target addition, washed once with room temperature PBS, and if required, non-internalized beads labeled by the addition of 1 μl/ml Alexa-647-labeled streptavidin or 1:1000 Alexa-647-labeled anti-human/mouse Fab. Cells were then fixed for 20 min at room temperature with PBS+4% PFA and then blocked for 60 min using PBS+5% human serum or 5% bovine serum albumin; if permeabilized cells were required, 0.1% Triton X-100 was added during this step. Proteins of interest were labeled following blocking/permeabilization with a 0.5 μM Cell Proliferation Dye eFluor 670 for 5 min at room temperature. The ReCLIP reagent was then aspirated and crosslinked stopping by the addition of 10 μl of quenching buffer (5 mM l-cystein=20 mM Tris.Cl, pH 7.4) for 15 min. Cells were suspended in lysis buffer 250 mM sucrose, 10 mM HEPES, 3 mM MgCl2, 1 mM NaVO4, 1:50 DNase I, 0.25 mM PMSF, 200 mM okadaic acid, 10 mM NaF, phosSTOP and 1 x completeMix phosphatase/protease inhibitors), transferred to an ice-cold nitrogen (Ca2+) buffer and lysed using a 10 μl, 300 PSI cavitation. Effe ronos and phagosomes were then recovered using a magnetic column, washed 3 x in lysis buffer and solubilized for 30 min at 37 °C in 30 μl of Laemmli buffer+50 mM DTT and 1 x phosSTOP/CompleteMix phosphatase/protease inhibitors.

Recoverer effe ronos and phagosomal proteins were boiled for 5 min, loaded onto a precast 4–20% gradient SDS-PAGE gel and separated for 3 h at 100 V. Gels were then fixed for 2 h in 40% ethanol+10% glacial acetic acid, incubated overnight with coloidal Coomassie Blue and destained in ddH2O for 3 h with gentle agitation. Gels were stored in ddH2O at 4 °C before mass spectrometry. Protein bands unique to the phagosome or efferosome lanes were then picked using an Ettan Robotic Spot-Picker (GE Health Sciences, Baie d'Urfe, Qu, Canada). Gel slices were desiccated with 50 mM ammonium bicarbonate and 50% acetonitrile, treated with 10 mM DTT and 55 mM iodoacetamide, and digested with trypsin. Peptides were extracted by a solution of 0.1% formic acid and 2% acetonitrile and freeze dried. Digestion samples were then suspended in a solution of 10% acetonitrile and 0.1% trifluoroacetic acid. Mass spectrometry analysis of each sample was performed using an AB Sciex 5800 TOF/TOF System (Framingham, MA, USA). Raw mass spectrometry data analysis was performed using Mascot database search (http://www.matrixscience.com).
Phagosome cargo sorting by Rab17

C Yin et al

Rab17 to the PM-RFP/target structure was then measured at all subsequent time points, and normalized to the maximum intensity Rab17 structure in the cell.

Colocalization of signaling molecules with phagosomes and effectorsof in fixed cells was quantified using a similar technique. 2-stack images of cells were captured and deconvolved using an iterative deconvolution approach. A region of interest (ROI) was manually drawn around each cell and the mean ± S.E.M. of the fluorescence intensity of each channel within the ROI determined. Phagocytic/effectoral targets were then identified using the local background subtraction and thresholding approach described above, but using the ‘bwlabel’ MATLAB command to identify targets in the 3D images. Each target was converted into a 3D ROI by identifying the bounding pixels of each target using the ‘connhull’ command. These ROIs were then expanded by a factor of 1.4 ×, which was determined experimentally to increase ROI size such that the bounding PM-RFP and any recruited signaling molecules would be captured without significant inclusion of cytosolic staining (data not shown). Targets were scored as associated with a molecule of interest if the mean intensity of the molecule within each ROI was 2 S.D. higher than the mean intensity of the ROI that did not contain the molecule throughout the entire cell. As with the live cell analyses, no intensity adjustments other than a global background subtraction were applied to the images of the signaling molecules to preserve linearity of the image intensity data.

Statistics. GraphPad Prism software (GraphPad Software, La Jolla, CA, USA) was used for all statistical tests. Unless otherwise noted, ANOVA with Tukey’s correction was used for analysis. Data are presented as mean ± S.E.M. P-values ≤ 0.05 are considered to be significant and are indicated by an asterisk.

Conflict of Interest

The authors declare no conflict of interest.

Acknowledgements. We thank Dr. Ronald S Flannagan (University of Western Ontario) for his extensive advice on this study. This study was funded by a Canadian Institutes for Health Research (CIHR) Operating Grant (MOP-123419) and Ontario Ministry of Research and Innovation Early Research Award (to BH). CY is funded by a CIHR MD/PhD Studentship and a CIHR CGS-M Scholarship.
