A recent report that sulfur hydride under pressure is an electron-phonon superconductor with a $T_c$ of 190 K has been met with much excitement although it is yet to be confirmed. Based on several electron-phonon spectral density functions already available from density functional theory, we find that the electron-phonon spectrum is near optimum for $T_c$ with a particularly large value of its characteristic phonon energy $\omega_n$, which is due to the small hydrogen mass. We find that the thermodynamic universal BCS ratios are near those for Pb and Nb-Sn. We suggest that optical measurements could be a useful tool to establish the existence and nature of the superconductivity in this system. Conventional superconductors are in the impurity-dominated dirty limit. By contrast sulfur hydride will be in the clean limit because of its large energy gap scale. The AC optical conductivity will display distinct and separate signatures of the superconducting gap in the low-energy impurity-dominated range of the optical spectrum and additional phonon structures at higher energies where the clean limit applies.

The observation\cite{1,2} of a dramatic and sharp drop in resistivity around a temperature of $T \lesssim 190$K in a sulfur hydride sample under $\sim 200$ GPa, has led to a flurry of new theoretical works\cite{3,4}. The verification that it is definitely superconducting, for example through the observation of a Meissner effect, still awaits further experiments, however, the authors did observe that with the application of a magnetic field of 7 Tesla there was a shift, to lower temperature, of the onset of the resistivity drop by $\sim 10$ K. Moreover, the conductivity below 190 K was found to be better than that of the purest metal at low temperature and was two orders of magnitude larger than that of pure copper.

A number of papers\cite{5,6,7} based on density functional theory for sulfur hydride have already provided detailed information on the electron-phonon spectral density function $\alpha^2 F(\omega)$ and have identified H$_2$S as the most likely phase involved at that pressure. While some quantitative differences exist between the various spectral densities available, all calculations support the idea of phonon-mediated superconductivity in H$_2$S with a $T_c$ of order 200 K at $\sim 200$ GPa. Still it remains essential to find ways to directly verify such a possibility. Lacking definitive confirmation, it is instructive to place H$_2$S within the context of the family of known conventional superconductors\cite{8}. In particular an emphasis on differences and commonalities between H$_2$S and the well-established cases of electron-phonon-mediated superconductivity can provide valuable insight. It is also important to calculate the expected properties of the superconducting state of H$_2$S with the specific aim of providing information that can be used by experimentalists to establish that H$_2$S is indeed a superconductor and to discover the pairing mechanism involved, i.e., the glue that binds the Cooper pairs.

In this Rapid Communications, we demonstrate that H$_2$S is a very highly optimized electron-phonon superconductor for various reasons and we provide a calculation of the optical conductivity as a test for identifying the superconducting gap and the Holstein structure for the phonon spectrum. For this purpose, we work with the $\alpha^2 F(\omega)$ spectrum provided in the literature. For illustrative purposes we have used the one developed by Errea et al\cite{4} (shown in Fig. S1) which includes anharmonic phonon effects. However, in the Supplemental Material\cite{9} (Fig. S1), we also show the spectra for the harmonic version from Errea et al. along with that from Flores-Livas et al\cite{10} for comparison (the one from Duan et al\cite{11} is also similar but not shown). Using the $\alpha^2 F(\omega)$, one can calculate the electron-phonon mass renormalization parameter, $\lambda = \int_0^\infty [\alpha^2 F(\omega)/\omega]d\omega$, the area under the spectrum $A = \int_0^\infty \alpha^2 F(\omega)d\omega$ and the Allen-Dynes characteristic phonon frequency\cite{12,13}, $\omega_n = \exp[(2/\lambda) \int_0^\infty [\ln(\omega)\alpha^2 F(\omega)/\omega]d\omega]$ which would equal $\omega_F$ if the $\alpha^2 F(\omega) = A\delta(\omega - \omega_F)$. For our digitization of the published spectrum shown in Fig. S1, $\lambda = 1.67$, $A = 118.5$ meV, and $\omega_n = 122$ meV. Comparison of these characteristic properties with the other spectra are given in Table S1 of the Supplemental Material. [Note, these spectra were digitized from the original papers and placed on a 2 meV grid. This gives characteristics that are in qualitative agreement with the original works if not always in perfect quantitative agreement. Such details do not impact our results and conclusions presented here. It is clear that all of the spectra are qualitatively similar\cite{14}. Calculating $T_c$ with these spectra using the standard s-wave electron-phonon Eliashberg equations\cite{9}, we find that for $T_c = 190$ K, the Coulomb pseudopotential $\mu^*$ would have to be 0.18 for the anharmonic spectrum and about 0.38-0.4 for the harmonic spectrum (or conversely, for a $\mu^* \sim 0.16$, the harmonic spectra would give a $T_c$ of order 250 K, which has been noted by the authors of these}
spectra). While a large $\mu^*$ is unusual, such a value has been found for the alkali-doped fullerenes and can be taken as an argument for strong electron correlations to be important in addition to the electron-phonon interaction. It should be noted that the spectrum of Flores-Livas is one that has been developed and used by accounting for a nonconstant energy-dependent electronic density of states and yet it essentially agrees with the Errea harmonic spectrum. These details aside and working with the anharmonic spectrum for illustration, we argue that the $\alpha^2 F(\omega)$ for H$_3$S is one of the most highly optimized among conventional superconductors.

One test of this concept is to evaluate the functional derivative of $T_c$ [Ref. $^{[2]}$] with respect to this spectrum as is shown in Fig. $^{[3]}$ (a) (red curve). This derivative is peaked at $\omega \sim 7k_BT_c$ and illustrates that if one could move all the spectral weight in the $\alpha^2 F(\omega)$ to a delta function placed at this frequency, then one would obtain the highest $T_c$ possible from this spectrum. However, the spectrum is distributed around this point and so the question remains as to how optimized is it? Using the characteristic phonon energy $\omega_{ln}$ as a measure, one finds that it is very close to the value of $7T_c$ as shown in the figure. Consequently, the spectrum is quite highly optimized already. This is understood from the fact that the functional derivative varies quite slowly about its peak and much of the weight of the $\alpha^2 F(\omega)$ falls in the region of this slow variation. The shape of the functional derivative speaks to the physics that for phonon frequencies that are too low, the phonons do not respond fast enough to pair the electrons, but rather act more like static impurities. Alternatively, at very high frequencies, the ions would wiggle too fast to have any net displacement or polarization to glue the Cooper pairs. As a result the optimal frequency is found at some intermediate frequency. A simple physical argument for the maximum to occur at $\omega \sim 7k_BT_c$ can be found in Refs. $^{[2,4,8]}$.

The question as to how optimal this spectrum is can be quantified by examining Fig. $^{[3]}$ (b) where the dimensionless ratio of $T_c/A$ is plotted versus $\mu^*$. The line with the open circles is the maximum value that $T_c$ could take for fixed $A$ as a function of $\mu^*$ and is calculated by placing a delta function of weight $A$ at the frequency of the peak in its own functional derivative and finding the $T_c$. This is a classic curve taken from Leavens and the solid black dots represent the data for several conventional superconductors taken from a tabulation (Table IV) in Ref. $^{[3]}$. The gold star shows where the spectrum in Fig. $^{[3]}$ (a) sits and it is just below the optimal line. Indeed, it falls only 8% below the theoretical absolute upper bound allowed to any spectrum with that area $A$ and $\mu^*$. Furthermore, the blue curve, shows how $T_c$ would vary for this spectrum as a function of $\mu^*$ and it is clear that it would always remain close to the upper bound. For $\mu^* = 0$, the $T_c = 298$ K.

One may now try to understand from this why the $T_c$ is so high. It is the unusually large value of $A$ in H$_3$S which accounts for the large $T_c$ found in this system. This sizable $A$ comes about because the electron-ion coupling remains large to very high phonon energies. In turn, the unusually large value of $\omega_{ln}$ is traced to the small hydrogen mass and the stiffness of the H-S bond stretching mode. Moreover, the lack of an electronic core structure to the hydrogen (see particularly Ref. $^{[4]}$) means that there is no orthogonalization of the conduction electron wavefunctions which in ions with core electrons effectively changes the electron-ion interaction potential into a weakened pseudopotential. These two facts combined provide the mechanism for a large area $A$ under the spectral density $\alpha^2 F(\omega)$ which extends to high energies with large magnitude. Further insight into the importance of a large $\omega_{ln}$ can be obtained through an analysis based

![Graph](image-url)
on the asymptotic formula for $T_c$ of Eliashberg theory derived on the assumption of a very large value of $\lambda$, the mass enhancement factor. In this limit $T_c = 0.182\sqrt{\omega_0T}$. We see that increasing $\lambda$ by a factor of 2 increases $T_c$ by $\sim 40\%$ while increasing $\omega_0$ by 2 doubles the $T_c$. While $\lambda$ is not in the asymptotic limit of large $\lambda$, this analysis nevertheless provides a useful qualitative picture. While $\lambda$ for $\text{H}_2\text{S}$ is not particularly large as compared with other electron-phonon superconductors, $\omega_0$ is quite significant at about 120 meV. Through the numerical solution of the Eliashberg equations for many model spectra, Leavens and Carbotte observed that, for $\lambda$ and $\mu^*$ in the range of $1.2 < \lambda < 2.4$ and $0.1 < \mu^* < 0.15$, a remarkably simple relationship between $T_c$ and $\lambda$ applied, namely $T_c = 0.148A$. This formula can be used to obtain further understanding of the role various ranges of the $\alpha^2F(\omega)$ spectrum play in $T_c$. As an example, the entire region below $\sim 165$ meV in the spectrum of Fig. S1(a) has an area of 39 meV while the area above is 80 meV, contributing, respectively, 67 and 137 K to the $T_c$ value. It is clear that the hydrogen bending vibrations and most importantly the stretching modes are critical for the high $T_c$ of $\text{H}_2\text{S}$ metallic phase.

In Fig. S2 we compare the gap ratio calculated for sulfur hydride with other conventional superconductors on a classic plot for the gap ratio versus $T_c/\omega_0$. We have done this calculation for both the anharmonic spectrum (gold star) and the two harmonic spectra shown in the Supplemental Material (with $T_c = 190$ K). Clearly, sulfur hydride fits well among the conventional superconductors and sits close to Pb and Nb$_3$Sn which are other highly optimized superconductors. Using this figure one can also translate to other figures for strong corrections to BCS ratios as found in Refs. 21, 22. We have done the numerical calculation and find for the anharmonic spectrum the specific heat ratio $\Delta C(T_c)/\gamma T_c = 2.53$ and the magnetic field ratio $\gamma T_c^2/H_0^2(0) = 0.136$, which are very close to the values found for Pb, as expected from Fig. S2.

We conclude from this that sulfur hydride appears to be a very highly optimized electron-phonon superconductor which uses the high phonon frequency of the hydrogen and large electron-ion interaction to obtain a high $T_c$. Nonetheless, it remains a question as to how to demonstrate the superconductivity and verify the electron-phonon interaction. Given that the sample is under pressure, many typical experimental probes may not be used. Tunneling was the classic experiment in conventional superconductors but here the energy scales are much higher than those that are usually accessed with tunneling. Consequently, an experiment which is non-contact but can probe high energy scales is needed. Here one is further helped by the fact that the material will be in the “clean limit”, where $2\Delta_0 \gg 1/\tau$ with $1/\tau$ being the impurity scattering rate. An excellent probe in this case, then, is optical conductivity measurements as they may be done on a sample in a high pressure cell. As the cuprate superconductors have already illustrated, the clean limit allows one to see boson structure in optics. This is illustrated in Fig. S3 where we show our calculation for the optical conductivity for the anharmonic spectrum of $\text{H}_2\text{S}$. [A comparison with that from the other $\alpha^2F(\omega)$ spectra is given in Fig. S2]. Shown are the superconducting and normal state curves for $T = 0.1T_c$. In the latter case, $\Delta$ is set to zero in the calculation and this curve is shown at the same temperature to illustrate differences between the two states independent of temperature. [For the normal state at $T_c$, which is not that different, see Fig. S3 of the Supplemental Material.] While the normal state shows a Drude absorption followed by a bump associated with the main source of inelastic scattering from the 200 meV peak in the electron-phonon spectrum (see Fig. S1), the superconducting state is much more dramatic. Here one sees a sharp impurity-dominated peak at the gap edge of $2\Delta_0 = 73$ meV and then a series of absorption peaks. This structured absorption can be traced to the $\alpha^2F(\omega)$ spectrum which we show in Fig. S3 shifted along the fre-
In Eliashberg theory, it was found that a critical parameter which measures coupling strength is the dimensionless ratio $T_c/\omega_n$. For small values of this ratio BCS theory is recovered while strong coupling corrections to the universal dimensionless ratio of BCS increase with increasing value of $T_c/\omega_n$. For H$_3$S, one finds a value near 0.13 which is close to that found in Pb, Nb$_3$Sn and others. It corresponds to the case where $\omega_n$ is close to the maximum in the functional derivative $T_c/\omega_n \approx 7$ and hence accounts for the near optimization of the spectrum. This also implies that the thermodynamic properties of H$_3$S will be close to those of Pb and Nb$_3$Sn. This does not imply, however, that other properties of their superconducting state will be similar. As an example, optical properties in H$_3$S will be very different from those in other conventional superconductors which are in the dirty (impurity-dominated) limit. Instead, because of the very large energy scale associated with its phonons and its superconducting gap value, H$_3$S is in the clean (phonon-dominated) regime. To be more precise, the absorptive part of the AC longitudinal conductivity $\text{Re} \sigma_{xx}(\Omega)$ as a function of photon energy $\Omega$ will show two distinct and separate regimes. At the energy of twice the gap, the regime remains impurity-dominated and there is a very sharp rise in absorption at $\Omega = 2\Delta$, but this is followed by dominant phonon-assisted absorption structures extending to many times $2\Delta$ which is usually referred to as the clean limit regime because residual impurity scattering plays a significant role. This region provides a detailed picture of the pairing glue. Consequently, optics can be used to provide information not only on the existence of superconductivity but also of the driving mechanism.

We thank T. Timusk for discussions, and B. Pavlovic and C. Tabert for assistance with figures. This work has been supported by the Natural Sciences and Engineering Research Council (NSERC) of Canada and, in part, by the Canadian Institute for Advanced Research (CIFAR).

Shown in Fig. S1 are three of the $\alpha^2 F(\omega)$ spectra available in the literature. The upper spectrum is a harmonic spectrum from Flores-Livas et al. [Ref. 4] and the lower two are from Errea et al. [Ref. 3]. There is also a harmonic spectrum from Duan et al. [Ref. 2] which is not shown here. These spectra were digitized from the original papers and placed on a 2 meV grid which give characteristics that are in qualitative agreement with the original works if not always in perfect quantitative agreement. Such details do not impact our results and conclusions presented here. It is clear that all of the spectra are qualitatively similar.

For our calculations, we have used the standard numerical solutions of the imaginary axis s-wave Eliashberg equations in order to solve for $T_c$ and other thermodynamic quantities. By an analytic continuation to the real axis, we evaluated the energy gap and the optical conductivity. A description of these techniques and formulas can be found in the review by Carbotte [Ref. 9]. The optical conductivity calculation is done following the procedure outlined by Akis et al. [Ref. 21].

In the following table we show the characteristic parameters of our digitized spectra.

In Fig. S2 we show the conductivity spectra for each of the $\alpha^2 F(\omega)$ shown in Fig. S1. To examine the effects of temperature, we show the conductivity for the anharmonic spectrum at several temperatures in Fig. S3.

### TABLE S1. Table of parameters for various digitized spectra

| $\alpha^2 F(\omega)$ | Errea harmonic | Errea anharmonic | Flores-Livas harmonic |
|-----------------------|----------------|------------------|-----------------------|
| $\lambda$             | 1.67           | 2.55             | 2.47                  |
| $\omega_{in}$ (meV)   | 122.1          | 102.6            | 106.1                 |
| $\omega_{max}$ (meV)  | 254            | 218              | 224                   |
| $\Delta$ (meV)        | 118.5          | 146.6            | 148.7                 |
| $T_c$ (K)              | 190            | 190 (249)$^a$    | 190 (255)             |
| $\mu^*(N=6)$           | 0.18           | 0.38 (0.16)      | 0.40 (0.16)           |
| $T_c/\omega_{in}$     | 0.134          | 0.16 (0.209)     | 0.154 (0.207)         |
| $\omega_{in}/T_c$     | 7.46           | 6.27 (4.79)      | 6.48 (4.83)           |
| $T_c/A$               | 0.138          | 0.112 (0.146)    | 0.110 (0.148)         |
| $\Delta_0$            | 36.5           | 39.9             | 39.1                  |
| $2\Delta_0/k_BT_c$    | 4.46           | 4.87             | 4.78                  |

$^a$ Entries in brackets correspond to taking $\mu^* = 0.16$. Of the $\alpha^2 F(\omega)$ shown in Fig. S1, To examine the effects of temperature, we show the conductivity for the anharmonic spectrum at several temperatures in Fig. S3.
FIG. S3. (Color online) Variation of the real part of the conductivity in the superconducting state for the anharmonic spectrum. Curves are shown for different temperatures as indicated. The red curve is for $T = T_c$ which is the normal state.
