Abstract

We have implemented a Langevin approach for the transport of heavy quarks in the UrQMD hybrid model. The UrQMD hybrid approach provides a realistic description of the background medium for the evolution of relativistic heavy ion collisions. We have used two different sets of drag and diffusion coefficients, one based on a $T$-Matrix approach and one based on a resonance model for the elastic scattering of heavy quarks within the medium. In case of the resonance model we have investigated the effects of different decoupling temperatures of the heavy quarks from the medium, ranging between 130 MeV and 180 MeV. We present calculations of the nuclear modification factor $R_{AA}$, as well as of the elliptic flow $v_2$ in Au+Au collisions at $\sqrt{s_{NN}} = 200$ GeV and Pb+Pb collisions at $\sqrt{s_{NN}} = 2.76$ TeV. To make our results comparable to experimental data at RHIC and LHC we have implemented a Peterson fragmentation and a quark coalescence approach followed by the semileptonic decay of the D- and B-mesons to electrons. We find that our results strongly depend on the decoupling temperature and the hadronization mechanism. At a decoupling temperature of 130 MeV we reach a good agreement with the measurements at both, RHIC and LHC energies, simultaneously for the elliptic flow $v_2$ and the nuclear modification factor $R_{AA}$. 

I. INTRODUCTION

One major goal of ultra-high-energy heavy-ion physics is to recreate the phase of deconfined quarks and gluons (the Quark Gluon Plasma, QGP) as it might have existed a few microseconds after the Big Bang. Various experimental facilities have been built to explore the properties of this QGP experimentally, while on the theory side a multitude of (potential) signatures and properties of the QGP have been predicted [1–3].

Heavy quarks are an ideal probe for the QGP. They are produced in the beginning of the collision in hard processes and therefore probe the created medium during its entire evolution. When the system cools down they hadronize, and their decay products can finally be detected. By investigating heavy-quark observables we can thus explore the interaction processes within the hot and dense medium. Two of the most interesting observables are the nuclear modification factor, \( R_{AA} \), and the elliptic flow, \( v_2 \). Experimentally, the nuclear modification factor shows a large suppression of the open heavy-flavor particles’ spectra at high transverse momenta (\( p_T \)) compared to the findings in pp collisions. This indicates a high degree of thermalization also of the heavy quarks with the bulk medium consisting of light quarks and gluons and, perhaps at the later stages of the fireball evolution, the hot and dense hadron gas. The measured large elliptic flow, \( v_2 \), of open heavy-flavor mesons and the non-photonic single electrons or muons from their semileptonic decay underlines this interpretation because it indicates that heavy quarks take part in the collective motion of the bulk medium. A quantitative analysis of the degree of thermalization of heavy-quark degrees of freedom in terms of the microscopic scattering processes may lead to an understanding of the mechanisms underlying the large coupling strength of the QGP and the corresponding transport properties.

In this paper we explore the medium modification of heavy-flavor \( p_T \) spectra, using a hybrid model, consisting of the Ultra-relativistic Quantum Molecular Dynamics (UrQMD) model [4, 5] and a full (3+1)-dimensional ideal hydrodynamical model [6, 7] to simulate the bulk medium. The heavy-quark propagation in the medium is described by a relativistic Langevin approach [8]. Similar studies have recently been performed in a thermal fireball model with a combined coalescence-fragmentation approach [8–14], in an ideal hydrodynamics model with a lattice-QCD EoS [15, 16], in a model from Kolb and Heinz [17], in the BAMPS model [18, 19], the MARTINI model [20] as well as in further studies and model comparisons [21–25].

The use of the UrQMD hybrid model provides a major step forward as compared to simplified expanding fireball models employed so far. It provides a realistic and well established background, including event-by-event fluctuations and has been shown to describe well many collective properties of relativistic heavy-ion collisions. For the heavy-quark propagation we apply a Langevin approach. Within this framework we investigate the effects of using different drag and diffusion coefficients and different freeze-out temperatures of heavy flavors on the heavy-quark observables and compare the results with the experimental data from the Relativistic Heavy Ion Collider (RHIC) and the Large Hadron Collider (LHC).

II. THE URQMD HYBRID MODEL

To extract information on the interaction of heavy quarks with the medium one ideally applies a well tested model for the (collective) dynamics of the bulk matter. In heavy-ion collisions the medium is by no means homogeneous. Rather it is a locally and event-by-event fluctuating, fast expanding system. In our calculation we employ the state of the art UrQMD hybrid model for the description of the expanding background. This model has been developed in the past years to combine the advantages of hadronic transport theory and ideal fluid dynamics [20]. To account
for the non-equilibrium dynamics in the very early stage of the collision in the hybrid model, the UrQMD cascade \cite{4, 5} is used to calculate the initial states of the heavy ion collisions each to be used in a subsequent hydrodynamical evolution \cite{27}. The transition from the UrQMD initial state and the hydrodynamical evolution takes place at a time $t_{\text{start}} = 2R/\sqrt{\gamma^2_{\text{CM}} - 1}$ i.e., after the two Lorentz-contracted nuclei have passed through each other ($\gamma_{\text{CM}}$ is the center-of-mass-frame Lorentz factor, and $R$ is the radius of the nucleus). The energy, baryon number, and momenta of all particles within UrQMD are mapped onto a spatial grid for the hydrodynamic evolution including event-by-event fluctuations. The full (3+1)-dimensional ideal hydrodynamic evolution is performed using the SHASTA algorithm \cite{6, 7}. We solve the equations for the conservation of energy and momentum and for the conservation of the baryonic charge. With $T^{\mu\nu}$ denoting the relativistic energy-momentum tensor the corresponding equations read

$$\partial_\mu T^{\mu\nu} = 0, \quad (1)$$

and for the baryon four-current $N^\mu$

$$\partial_\mu N^\mu = 0. \quad (2)$$

To transfer all particles back into the UrQMD model, an approximate iso-eigentime transition is chosen (see \cite{28} for details). Here, we apply the Cooper-Frye prescription \cite{29} and transform to particle degrees of freedom via

$$E \frac{dN}{d^3p} = g_i \int d\sigma_\mu \ p^\mu f(x,p). \quad (3)$$

Here $d\sigma_\mu = (d^3x, 0, 0, 0)$ is the hypersurface normal. In Eq. (3) $f(x,p)$ are the Bose- and Fermi-distribution functions and $g_i$ the degeneracy factors for the different particle species. After the “particlization” the evolution proceeds in the hadronic cascade (UrQMD), where final re-scatterings and decays are calculated until all interactions cease and the system decouples.

A more detailed description of the hybrid model including parameter tests and results can be found in \cite{26}. A comparison to the results employing the non-approximated hypersurface can be found in \cite{30}.

### III. HEAVY-QUARK DIFFUSION

The diffusion of a “heavy particle” in a medium consisting of “light particles” can be described with a Fokker-Planck equation \cite{9, 21, 31–35}. Here one approximates the collision term of the corresponding Boltzmann equation, which in turn can be mapped into an equivalent stochastic Langevin equation.

#### A. Relativistic Langevin approach

In the relativistic realm such a Langevin process reads

$$\text{d}x_j = \frac{p_j}{E} \text{d}t, \quad \text{d}p_j = -\Gamma p_j \text{d}t + \sqrt{\text{d}t} C_{jk} \rho_k. \quad (4)$$

Here $\text{d}t$ is the time step in the Langevin calculation, $\text{d}x_j$ and $\text{d}p_j$ are the coordinate and momentum changes in each time-step, $E = \sqrt{m^2 + \vec{p}^2}$, and $\Gamma$ is the drag or friction coefficient. The covariance
matrix, \( C_{jk} \), of the fluctuating force is related to the diffusion coefficients, as we shall see below. Both \( \Gamma \) and \( C_{jk} \) depend on \( (t, x, p) \) and are defined in the (local) rest-frame of the fluid. The \( \rho_k \) are Gaussian-normal distributed random variables. Their distribution function reads

\[
P(\rho) = \left( \frac{1}{2\pi} \right)^{3/2} \exp \left( -\frac{\rho^2}{2} \right).
\]

(5)

with \( \rho = (\rho_1, \rho_2, \rho_3) \). The fluctuating force \( F^{(fl)}_j \) thus obeys

\[
\langle F^{(fl)}_j(t) \rangle = 0, \quad \langle F^{(fl)}_j(t)F^{(fl)}_k(t') \rangle = C_{jl}C_{kl} \delta(t - t').
\]

(6)

It is important to note that with these specifications the random process is not yet uniquely determined since one has to specify, at which momentum argument the covariance matrix \( C_{jk} \) has to be taken to define the stochastic time integral in (4). Thus, we set

\[
C_{jk} = C_{jk}(t, x, p + \xi dp).
\]

(7)

For \( \xi = 0, \xi = 1/2, \) and \( \xi = 1 \) the corresponding Langevin processes are called the pre-point Ito, the mid-point Stratonovic-Fisk, and the post-point Ito (or Hänggi-Klimontovich) realization, respectively [36].

According to (4) and (6), for a given value of \( \xi \) in (7) the average of an arbitrary observable \( g(x, p) \) obeys the time-evolution

\[
\langle g(x + dx, p + dp) - g(x, p) \rangle = \left\langle \frac{\partial g}{\partial x_j} E \frac{\partial g}{\partial p_j} \left( -\Gamma p_j + \xi \frac{\partial C_{jk}}{\partial p_l} C_{kl} \right) \right\rangle dt + O(dt^{3/2}).
\]

(8)

Here all momentum arguments of the drag and diffusion coefficients have to be taken at \( p \). From (8) it follows immediately that the time evolution of the phase-space distribution function \( f_Q(t, x, p) \) of heavy quarks is given by the Fokker-Planck equation,

\[
\frac{\partial f_Q}{\partial t} + \frac{p_j \partial f_Q}{E \partial x_j} = \frac{\partial}{\partial p_j} \left[ \left( \Gamma p_j - \xi C_{kl} \frac{\partial C_{jk}}{\partial p_l} \right) f_Q \right] + \frac{1}{2} \frac{\partial^2}{\partial p_j \partial p_k} (C_{jl}C_{kl} f_Q).
\]

(9)

Thus, the usual drag and diffusion coefficients for an isotropic medium are related to the pertinent parameters in the Langevin process by

\[
Ap_j = \Gamma p_j - \xi C_{lk} \frac{\partial C_{jk}}{\partial p_l},
\]

(10)

\[
C_{jk} = \sqrt{2B_0} P^\parallel_{jk} + \sqrt{2B_1} P^\perp_{jk},
\]

(11)

with \( P^\parallel_{jk} = \frac{p_jp_k}{p^2}, \quad P^\perp_{jk} = \delta_{jk} - \frac{p_jp_k}{p^2} \).

(12)

In case of a homogeneous static background (“heat bath”), the stationary limit should become a Boltzmann-Jüttner distribution with the temperature of the “heat bath”. Thus, one typically adjusts the drag coefficient by choosing the longitudinal diffusion coefficient, \( B_1 \), in (11) such as to

---

1 In numerical studies it has turned out that drag and diffusion coefficients as obtained from microscopic models usually do not lead to the expected long-time stationary limit of the phase-space distribution for the heavy particles when diffusing in an equilibrated background medium.
satisfy this asymptotic equilibration condition, leading to dissipation-fluctuation relations between
this diffusion coefficient and the drag coefficient \[2\] [21].

It turns out that for \(B_0 = B_1 = D(E)\) and a homogeneous background medium the Boltzmann-
Jüttner distribution,

\[
f_{Q}^{(eq)}(p) = \exp \left( -\frac{E}{T} \right), \quad \text{with} \quad E = \sqrt{p^2 + m^2},
\]

becomes a solution of the corresponding stationary Fokker-Planck equation, if the dissipation-
fluctuation relation

\[
\Gamma(E)ET - D(E) + T(1 - \xi)D'(E) = 0,
\]

in (14) is fulfilled. A straightforward way to achieve the correct asymptotic equilibrium distribution within
a relativistic Langevin simulation is to set \(\xi = 1\) (i.e., using the post-point Ito realization). This
reduces \[14\] to

\[
D(E) = \Gamma(E)ET.
\]

For applications to heavy-ion collisions we use \(\Gamma\) and \(B_0\) from underlying microscopic models for
heavy-quark scattering with light quarks and gluons as detailed below and adjust the longitudinal
diffusion coefficient to

\[
B_1 = \Gamma ET.
\]

So far we have defined our Langevin process with respect to the (local) rest frame of the background
medium. For a medium with collective flow, one has to evaluate the time-step in the local rest-
frame and boost-back to the computational frame. For a closer look on the post-point description
see section VIIA.

For the heavy-quark propagation in the Langevin model we also need transport coefficients. In
this work these drag and diffusion coefficients are obtained from two non-perturbative models for
elastic heavy-quark scattering, a resonance model, where the existence of D-mesons and B-mesons
in the QGP phase is assumed, as well as a \(T\)-Matrix approach in which quark-antiquark potentials
are used for the calculation of the coefficients in the QGP. They are described in detail in Sec.
VII B and are shown in Fig. 1 as function of the three-momentum \(|\vec{p}|\) at \(T = 180\) MeV and in Fig.
2 as function of the temperature at a fixed three-momentum of \(|\vec{p}| = 0\).

B. Implementation of the Langevin simulation into the UrQMD-hybrid model

For the present study, charm production and propagation is evaluated perturbatively on the
time-dependent background generated by UrQMD/Hybrid. To model a fluctuating and space-time
dependent Glauber-initial state geometry, we perform a first UrQMD run with elastic 0° scatterings
between the colliding nuclei and save the nucleon-nucleon collision space-time coordinates. These
coordinates are used in a second, full UrQMD run as (possible) production coordinates for the
heavy quarks.

As momentum distribution for the initially produced charm quarks at \(\sqrt{s_{NN}} = 200\) GeV we use

\[
\frac{1}{2\pi p_T dp_T} = \frac{(A_1 + p_T^2)^2}{(1 + A_2 \cdot p_T^2)^{A_3}},
\]

(17)
FIG. 1. (Color online) Drag (left) and diffusion (right) coefficients in the resonance model and the T-Matrix approach for charm and bottom quarks. The plot shows the dependence of the coefficients on the three-momentum $|\vec{p}|$ at a fixed temperature of $T = 180$ MeV.

FIG. 2. (Color online) Drag (left) and diffusion (right) coefficients in the resonance model and the T-Matrix approach for charm and bottom quarks. The plot shows the dependence of the coefficients on the temperature at a fixed three-momentum $|\vec{p}| = 0$. The T-Matrix coefficients are calculated between 180 MeV and 360 MeV only.

with $A_1 = 0.5$, $A_2 = 0.1471$ and $A_3 = 21$ and for bottom quarks

$$\frac{1}{2\pi p_T} \frac{dp_T}{dt} = \frac{1}{(A_1 + p_T^2)^{A_2}},$$

with $A_1 = 57.74$ and $A_2 = 5.04$. These distributions are taken from $[9, 37]$ and are shown in Fig. 3. They are obtained by using tuned $c$-quark spectra from PYTHIA. Their pertinent semileptonic single-electron decay spectra account for pp and dAu measurements by STAR up to 4 GeV. The missing part at higher $p_T$ is then supplemented by B-meson contributions.

Starting with these charm- and bottom-quark distributions as initial conditions we perform, as soon as the hydrodynamics start condition is fulfilled, an Ito post-point time-step of our Langevin simulation as described in Sec. III A at each time-step of the hydrodynamical evolution.

We use the cell velocities, cell temperatures, the length of the time-step and the $\gamma$-factor of the cells to calculate the momentum transfer, propagating all heavy quarks independently. For the Langevin transport we use the drag and diffusion coefficients obtained from the resonance model or T-Matrix approach as described in Sec. VIII B.

To analyze the sensitivity of $R_{AA}$ and especially $v_2$ on the decoupling time of the heavy fla-
FIG. 3. (Color online) Fits of D- and D*-meson $p_T$ spectra in 200 AGeV d-Au collisions at RHIC with a modified PYTHIA simulation (left panel) and the corresponding non-photonic single-electron $p_T$ spectra in p-p and d-Au collisions (taken from [38]). The missing yield of high-$p_T$ electrons is fitted with the analogous B-meson decay spectra, thus fixing the bottom-charm ratio at $\sigma_{b\bar{b}}/\sigma_{c\bar{c}} \simeq 4.9 \times 10^{-3}$.

vors from the medium we vary the decoupling temperatures between 130 MeV and 180 MeV (for the resonance model) and extrapolate the corresponding transport coefficients smoothly into the hadronic phase. This assumption of a smooth transition of the transport coefficients in the transition from the partonic description above and the hadronic one below $T_c$ has been verified, using an effective model for open-heavy-flavor interactions in a hadronic medium in [15, 39].

Our approach provides us with the heavy-quark momentum distribution. We include a hadronization mechanism for open-heavy-flavor mesons (D and B mesons). Since non-photonic single electrons are usually measured in experiments, we perform a semileptonic decay into electrons as final step to compare to data. In addition we also provide D- and B-meson results for direct comparisons to the upcoming direct D/B measurements by the STAR Heavy Flavor Tracker (HFT). These results are shown in Sec. VII C.

IV. RESULTS AT RHIC ENERGIES

A. Elliptic flow $v_2$ and nuclear modification factor $R_{AA}$ with fragmentation

Fig. 4 presents the elliptic flow, $v_2$, of charm and bottom quarks from Au+Au collisions at $\sqrt{s_{NN}} = 200$ GeV in the centrality range $\sigma/\sigma_{tot} = 20\%-40\%$ applying a rapidity cut of $|y| < 0.35$.

For our calculation using the drag and diffusion coefficients of the $T$-Matrix model we use a decoupling temperature of 180 MeV, while with the resonance model we show results for decoupling temperatures of 130 MeV, 150 MeV and 180 MeV.

As one can clearly see, the elliptic flow, $v_2$, of bottom quarks (dashed lines) is much smaller compared to that of the charm quarks (solid lines) due to their larger mass. Furthermore the use of the coefficients from the $T$-Matrix model compared with those from the resonance model shows that both calculations are in reasonable agreement. The elliptic flow of the charm quarks is nevertheless somewhat lower for the $T$-Matrix model than for the resonance model. When decreasing the decoupling temperature the flow clearly increases. Thus, we conclude that the late phase of the heavy-ion collision may have considerable influence on the heavy-flavor elliptic flow although the drag and diffusion coefficients become small in the late stages of the fireball evolution.

Moreover the, $v_2$, is shifted towards higher $p_T$ for lower decoupling temperatures. This effect is due to the increased radial velocity of the medium, which is in case of an developed elliptic flow
larger in $x$ than in $y$ direction. Consequently there is a depletion of particles with high $v_x$ in the low $p_T$ region and smaller elliptic flow. This effect is more important for heavier particles and a larger radial flow \[40, 41\].

To compare our calculations with data on non-photonic electrons from RHIC we perform a Peterson fragmentation of the charm and bottom quarks to D-mesons and B-mesons using the fragmentation function from \[42\],

$$D_H^J(z) = \frac{N}{z[1 - (1/z) - \epsilon_Q/(1 - z)]^2},$$

where $N$ is a normalization constant, $z$ the relative-momentum fraction obtained in the fragmentation of the heavy quark and $\epsilon_Q = 0.05(0.005)$ for charm (bottom) quarks. After hadronization we use PYTHIA routines for the semileptonic decay to electrons \[43, 44\].

Fig. 4 shows our results for the $v_2$ for single-electrons in comparison to data from the PHENIX collaboration.

![Graph showing $v_2$ vs $p_T$ for heavy quarks and electrons](image)

FIG. 4. (Color online) Left: Elliptic flow, $v_2$, of heavy quarks in Au+Au collisions at $\sqrt{s_{NN}} = 200$ GeV. We use a rapidity cut of $|y| < 0.35$. The solid lines depict the charm quarks while the dashed lines depict the bottom quarks.

Right: Elliptic flow, $v_2$, of electrons from heavy-meson decays using Peterson fragmentation to D/B mesons and subsequent decay into electrons in Au+Au collisions at $\sqrt{s_{NN}} = 200$ GeV. We use a rapidity cut of $|y| < 0.35$. Data are from \[45\].

Again we clearly observe the importance of the late phase of the collision. The depletion effect at low $p_T$ described before is clearly visible. The decrease of the elliptic flow at high $p_T$ is due to the increasing fraction of electrons from bottom decays, which have a lower $v_2$ as seen in Fig. 4. The calculated flow in the setup with the Peterson fragmentation is too small compared to the PHENIX data.

The corresponding nuclear modification factor, $R_{AA}$, for heavy quarks is shown in Fig. 5. Again we present results for Au+Au collisions at $\sqrt{s_{NN}} = 200$ GeV in the centrality range 20%-40%. The quenching for charm quarks is, as expected, much stronger than for bottom quarks. While for bottom quarks the suppression at high $p_T$ is moderate, $R_{AA}$ may drop to 20-30% for charm quarks. The influence of the medium is, as already seen in our flow calculations, larger for a lower decoupling temperature underlining the importance of the late phase of the collision. Fig. 5 shows the comparison of our non-photonic-electron $R_{AA}$ to the data taken by the PHENIX collaboration.

---

\[2\] However, recent preliminary PHENIX data presented at QM 2012 seem to suggest the contrary.

(Talk by T. Sakaguchi at QM 2012, data not published yet)
The nuclear modification factor drops quite rapidly and stabilizes at about $p_T \gtrsim 2$ GeV. Around $p_T \approx 2$ GeV it is significantly below the PHENIX data. For higher $p_T$ the calculated $R_{AA}$ approaches the measured data, especially for low decoupling temperatures. This effect is due to the increasing flow of the heavy-flavor particles with decreasing decoupling temperature, which pushes low-$p_T$ heavy-flavor particles towards higher $p_T$ bins.

### B. Elliptic flow $v_2$ and nuclear modification factor $R_{AA}$ using a $k$ factor

In the previous section we learned that the elliptic flow of the heavy quarks in the calculation with fragmentation is too small compared to experimental data. One possibility to improve on this problem may be to multiply the drag and diffusion coefficients with a "$k$ factor". Therefore we have performed the same calculations as in the last section but using a $k$ factor of 3.

As we see in Fig. 6 the elliptic flow increases considerably due to the stronger coupling of the heavy quarks to the hot medium. The results after performing the Peterson fragmentation and the subsequent decays to electrons are shown in Fig. 6. The elliptic flow is now comparable to the data, especially when using a low decoupling temperature of 130 MeV. Only at low $p_T$ we underestimate the flow due to the depletion effect described above.

Our results for the nuclear modification factor, $R_{AA}$, are depicted in Fig. 7. The quenching is much stronger than for the calculation without a $k$ factor. Fig. 7 shows the results for electrons. The suppression of non-photonic electrons at high $p_T$ is also stronger than for the calculation without a $k$ factor.

We conclude that the use of a $k$ factor can improve the description of the elliptic flow. However, it is not possible to reach a consistent simultaneous description of both, the elliptic flow and the nuclear modification factor using the same $k$ factor.

### C. Elliptic flow $v_2$ and nuclear modification factor $R_{AA}$ using Coalescence

Instead of describing heavy quark hadronization by Peterson fragmentation (and/or and additional $k$-factor, as discussed above) one can alternatively apply a quark coalescence approach for
FIG. 6. (Color online) Left: Elliptic flow, $v_2$, of heavy quarks in Au+Au collisions at $\sqrt{s_{NN}} = 200$ GeV employing a $k$ factor of 3. We use a rapidity cut of $|y| < 0.35$. The solid lines depict the charm quarks while the dashed lines depict the bottom quarks.

Right: Elliptic flow, $v_2$, of electrons from heavy quark decays in Au+Au collisions at $\sqrt{s_{NN}} = 200$ GeV employing a $k$ factor of 3. We use a rapidity cut of $|y| < 0.35$. The flow in our calculation using a $k$ factor is comparable to data [45].

D- and B-meson production. To implement this coalescence we perform the Langevin calculation until the decoupling temperature is reached. Subsequently we coalesce a light quark with a heavy quark. As the light quarks constitute the medium propagated by hydrodynamics, the average velocities of the light quarks can be (on average) approximated by the flow-velocities of the hydro cells. The mass of the light quarks is assumed to be 370 MeV so that the D-meson mass becomes 1.87 GeV when the masses of the light quarks and the charm quarks (1.5 GeV) are added. Since we assume the light quarks to have the same mass when coalescing with bottom quarks (4.5 GeV), the B-mesons obtain a mass of 4.87 GeV.

The differences of the flow and the spectra of D- and B-mesons when comparing Peterson fragmentation (without $k$-factor) to the coalescence model is shown in Fig. 8. These calculations are performed employing a decoupling temperature of 150 MeV.

As compared to the fragmentation case, the elliptic flow reaches higher values at high $p_T$ due
FIG. 8. (Color online) Elliptic flow $v_2$ (left) and $R_{AA}$ (right) of D mesons (solid lines) and B mesons (dashed lines) in Au+Au collisions at $\sqrt{s_{NN}} = 200$ GeV. We use a rapidity cut of $|y| < 0.35$. A comparison of a Peterson fragmentation and a coalescence with light quarks is shown. For the drag and diffusion coefficients we use the resonance model with a decoupling temperature of 150 MeV.

to the coalescence. Also the depletion effect described before is more pronounced. Regarding the nuclear modification factor, Fig. 8 the difference of Peterson fragmentation and the coalescence model is even larger. The push of low-$p_T$ particles to higher $p_T$ is stronger in case of the coalescence model, while the suppression of heavy mesons at high $p_T$ is stronger in case of Peterson fragmentation.

Again we perform a decay to electrons using PYTHIA to compare to experimental measurements from the PHENIX collaboration. Fig. 9 (left) shows our results for $v_2$. Due to the coalescence the elliptic flow is strongly increased compared to the previous calculation using the Peterson fragmentation. This higher flow is due to the momentum kick of the light quarks in the recombination process, which provides additional flow from the medium. For a decoupling temperature of 130 MeV we obtain a reasonable agreement with the experimental data.

In Fig. 9 (right) the nuclear modification factor for non-photon single electrons is depicted. Also here we obtain a good agreement with the data. Especially at moderate $p_T \sim 2$ GeV the calculation has strongly improved. The coalescence mechanism pushes the heavy quarks to higher $p_T$. As seen before we obtain the best agreement to data for rather low decoupling temperatures.
In conclusion we observe that the coalescence mechanism is required to describe experimental data with our Langevin model. Only with the coalescence model one is able to describe both $R_{AA}$ and $v_2$ consistently in the present model.

D. Dependence of the medium modification on the equation of state

The heavy-flavor-flow observables in Langevin simulations are quite sensitive to the used description of the background medium \cite{24}. To examine this issue somewhat further, we have performed our calculations also using different equations of state that are implemented in the UrQMD hybrid model. Our results for different equations of state for the drag and diffusion coefficients of the resonance model with a decoupling temperature of 150 MeV are shown in Fig. 10 for the elliptic flow $v_2$ and for the nuclear modification factor $R_{AA}$.

The equation of state we have been using for all results in the previous sections is the chiral EoS. It is constructed by matching a state of the art hadronic chiral model to a mean field description of the deconfined phase. The deconfinement transition in this approach is included by the means of an effective Polyakov Loop potential, coupling to the free quarks. It has been shown in \cite{46} that the chiral EoS gives a reasonable description of lattice QCD thermodynamics at $\mu_B = 0$ and can be extended to finite baryon densities. The Hadron resonance gas EoS resembles the active degrees of freedom that are also included in the UrQMD transport approach, namely most hadronic states and their resonances. The Bag model EoS \cite{7} follows from matching a Walecka type hadronic model to massless quarks and gluons via a Maxwell construction. It exhibits a strong first order phase transition for all values of $\mu_B$.

![Fig. 10](image)

**FIG. 10.** (Color online) Elliptic flow $v_2$ (left) and nuclear modification factor $R_{AA}$ (right) of heavy quarks in Au+Au collisions at $\sqrt{s_{NN}} = 200$ GeV. We use a rapidity cut of $|y| < 0.35$. Different equations of state are compared.

As one sees clearly the influence on the mediums evolution as seen through the heavy quarks for this set of equations of state is very small.

V. RESULTS AT LHC ENERGIES

In the previous sections we found that we reach the best agreement to experimental PHENIX data when using the Resonance model applying a decoupling temperature of 130 MeV and using quark coalescence as hadronization mechanism. Now we apply the same description also at LHC energies ($\sqrt{s_{NN}} = 2.76$ TeV). The momentum distribution for the initially produced charm quarks
at LHC is obtained from a fit to PYTHIA calculations. The fit function we use is

\[
\frac{dN}{d^2p_T} = \frac{1}{(1 + A_1 \cdot (p_T^2)^{A_2})^{A_3}}
\]

with the coefficients \(A_1 = 0.136\), \(A_2 = 2.055\) and \(A_3 = 2.862\).

We have performed our calculations in Pb+Pb collisions at \(\sqrt{s_{NN}} = 2.76\) TeV in a centrality range of 30%-50%. The analysis is done in a rapidity cut of \(|y| < 0.35\) in line with the ALICE data.

![Graph](image)

**FIG. 11.** (Color online) Left: Flow \(v_2\) of D-mesons in Pb+Pb collisions at \(\sqrt{s_{NN}} = 2.76\) TeV compared to data from the ALICE experiment. (Talk by Z. Conesa del Valle at QM 2012, data not published yet.) A rapidity cut of \(|y| < 0.35\) is employed.

Right: \(R_{AA}\) of D-mesons in Pb Pb collisions at \(\sqrt{s_{NN}} = 2.76\) TeV compared to experimental data from ALICE [47]. A rapidity cut of \(|y| < 0.35\) is employed.

Fig. 11 (left) depicts our results for the elliptic flow compared to ALICE measurements. The D-meson \(v_2\) exhibits a strong increase and reaches a maximum at about \(p_T = 3\) GeV with \(v_2 \sim 19\%\). The agreement between the ALICE measurements of \(D^0\)- and \(D^+\)-mesons and our calculation is quite satisfactory.

A complementary view on the drag and diffusion coefficients is provided by the nuclear suppression factor \(R_{AA}\). Figure 11 (right) shows the calculated nuclear modification factor \(R_{AA}\) of D-mesons at LHC. In line with the experimental data the simulation is done for a more central bin of \(\sigma/\sigma_{tot} = 0\%-20\%\). We find a maximum of the \(R_{AA}\) at about \(p_T = 2\) GeV followed by a sharp decline to an \(R_{AA}\) of about 0.2 at high \(p_T\). As we can see we can describe the data at medium \(p_T\) well but over-predict them at low \(p_T\) bins.

**VI. SUMMARY**

In this paper we have investigated the medium modification of heavy-quark \(p_T\) spectra in the hot medium created in heavy-ion collisions at RHIC and LHC energies on the basis of a Langevin simulation coupled to the UrQMD hybrid model. The aim of this study was to find a consistent description for both the elliptic flow, \(v_2\), and the nuclear modification factor, \(R_{AA}\), with a realistic dynamical description of the background medium. We have used two different sets of drag and diffusion coefficients, based on a \(T\)-Matrix approach and a resonance-scattering model for the elastic scattering of heavy quarks with light quarks and antiquarks. Both sets of coefficients lead to similar results for the heavy-flavor observables.
In the first part of our analysis we have used a fragmentation mechanism, the Peterson fragmentation, to describe the hadronization of heavy quarks to open-heavy-flavor mesons. We have found a low elliptic flow and a too strong heavy-flavor suppression at high $p_T$. Subsequently we have explored how a $k$ factor for the drag and diffusion coefficients would influence the results. We found that with $k = 3$, the description of $v_2$ is improved, but has lead to an even larger suppression of the nuclear modification factor $R_{AA}$, as expected. We conclude that a combination of fragmentation and a Langevin simulation with a $k$-factor in the transport coefficient does not allow for a consistent description of the data on non-photonic single electron spectra in Au+Au collisions ($\sqrt{s_{NN}} = 200$ GeV) at RHIC.

To overcome this problem we have used a coalescence approach to heavy-quark hadronization to open-heavy-flavor mesons instead of the fragmentation. The coalescence mechanism allows for a consistent description of both $v_2$ and $R_{AA}$. We have performed the simulations, assuming different decoupling temperatures of the heavy quarks from the medium, and found that the late phase of the collision can have a considerable effect on the heavy-quark observables. Within our study we find the best agreement to experimental data using a low decoupling temperature of 130 MeV. In Sec. V D we have also addressed the sensitivity of the heavy-flavor observables to the assumed equation of state of the strongly interacting medium. Here we find that our results are insensitive to variations of the particular equation of state used in UrQMD’s hydrodynamic model.

Finally we also explored the medium modification in our model at LHC energies. Here we could reach a good agreement to data for the elliptic flow $v_2$ of D-mesons. For the nuclear modification factor $R_{AA}$ we reach a good agreement at medium $p_T$, but seem to miss the data at low $p_T$ bins.

First measurements with the STAR Heavy Flavor Tracker (HFT) are scheduled for the year 2014. It will provide new, complementary measurements in heavy ion collisions at $\sqrt{s_{NN}} = 200$ GeV. The HFT will enable direct identification of heavy flavor meson decays like $D^0 \rightarrow K^-\pi^+$ or $D_s^+ \rightarrow K^-\pi^+K^+$. This is supposed to lead to better $v_2$ measurements down to very low $p_T$ and a better understanding of the energy loss of heavy quarks in the medium. Especially it will provide us with identified D-meson spectra which will enable us to compare our heavy-meson results to data separately for D- and B-mesons and therefore to get further insights on the hadronization mechanism.

VII. APPENDIX

A. Post-point Ito realization

Since the phase-space distribution of relativistic particles is a scalar \( f_{Q}^{(eq)} \), the proper equilibrium limit is given by the corresponding boosted Boltzmann-Jüttner phase-space distribution,

\[
\int d^{4}p \propto \exp \left( -\frac{p \cdot u}{T} \right),
\]

where \( u(t, x) \) is the four-velocity field of the medium and \( p \) the (on-shell) four-momentum of the heavy quark in the local rest-frame. It can be shown analytically, and we have numerically checked, that for obeying this constraint, one has to apply the post-point prescription, \( \xi = 1 \), strictly only to the momentum argument of the covariance matrix, \( C_{jk} \) as given in (7) and not to the corresponding coefficients originating from the Lorentz transformation of the time step \( dt \) with respect to the laboratory frame (bare symbols) to the one in the local rest-frame of the heat bath (starred symbols), i.e., in the transformation prescription for the time interval,

\[
dt^* = m \frac{E^*}{E} \, d\tau = m \frac{E}{E^*} \frac{E}{\rho \cdot u} \, dt,
\]

one has to use the heavy-quark momenta at time \( t \) without a post-point update rule. Here, \( d\tau \) denotes the scalar “proper-time” interval of the heavy quark, corresponding to the given time interval, \( dt \), with respect to the laboratory frame \([24]\).

B. Drag and diffusion coefficients

We use two non-perturbative models for elastic heavy-quark scattering in the quark-gluon plasma to evaluate the drag and diffusion coefficients for the Langevin simulation of heavy-quark diffusion.

The resonance model is based on heavy-quark effective theory (HQET) and chiral symmetry in the light-quark sector \([33]\). Motivated by the finding in lattice-QCD calculations that hadron-like bound states and/or resonances might survive the phase transition in both the light-quark sector (e.g., \( \rho \) mesons) and heavy quarkonia (e.g., \( J/\psi \)), in this model we assume the existence of open-heavy-heavy-flavor meson resonances like the D and B mesons.

In the \( T \)-Matrix approach static in-medium quark-antiquark potentials from lattice QCD are used as scattering kernels in a Brückner like \( T \)-matrix approach to calculate the scattering-matrix elements for elastic scattering of heavy quarks with light quarks and antiquarks \([9]\).

The heavy-light quark resonance model \([33]\) is based on the Lagrangian,

\[
\mathcal{L}_{D_{c,q}} = \mathcal{L}_{D}^{0} + \mathcal{L}_{c,q}^{0} - i G_S \left( \bar{q} \Phi^{1+} \frac{1 + \gamma^5}{2} c - \bar{q} \gamma^5 \Phi^{1+} \frac{1 + \gamma^5}{2} c + h.c. \right) - G_V \left( \bar{q} \gamma^\mu \Phi^{1+} \frac{1 + \gamma^5}{2} c - \bar{q} \gamma^5 \gamma^\mu \Phi^{1+} \frac{1 + \gamma^5}{2} c + h.c. \right),
\]

and an equivalent one for bottom quarks. Here \( v \) denotes the heavy-quark four-velocity. The free part of the Lagrangian is given by

\[
\mathcal{L}_{D_{c,q}} = \bar{c} (i \partial - m_c) c + \bar{q} i \partial q,
\]

\[
\mathcal{L}_{D}^{0} = (\partial_{\mu} \Phi^{+})(\partial^{\mu} \Phi^{1}) + (\partial_{\mu} \Phi^{1+})(\partial^{\mu} \Phi^{0}) - m_0^2 (\Phi^{1} \Phi + \Phi^{+} \Phi^{*}) - m_0^2 (\Phi^{1} \Phi + \Phi^{+} \Phi^{*}) - \frac{1}{2} (\Phi^{+} \Phi^{* \rho \mu} + \Phi^{1}_{\rho \mu} \Phi^{1*}_{\rho \mu}) + m_V^2 (\Phi^{1} \Phi^{+} + \Phi^{0} \Phi^{*}) + m_1^2 (\Phi^{1} \Phi^{+} + \Phi^{0} \Phi^{*}) + m_2^2 (\Phi^{1} \Phi^{+} + \Phi^{0} \Phi^{*}),
\]

(23)
where $\Phi$ and $\Phi_0^*$ are pseudo-scalar and scalar meson fields (corresponding to $D$ and $D_0^*$ mesons). Based on chiral symmetry, restored in the QGP phase, we also assume the existence of mass degenerate chiral-partner states. Further from heavy-quark effective symmetry one expects spin independence for both the masses, $m_S = m_V$, and the coupling constants, $G_S = G_V$. For the strange-quark states we take into account only the pseudo-scalar and vector states ($D_s$ and $D_s^*$, respectively).

The $D$-meson propagators are dressed with the corresponding one-loop self energy. Assuming charm- and bottom-quark masses of $m_c = 1.5$ GeV and $m_b = 4.5$ GeV, we adjust the masses of the physical $D$-meson-like resonances to $m_D = 2$ GeV and $m_B = 5$ GeV, in approximate agreement with the $T$-matrix models of heavy-light quark interactions in \cite{49, 50}. The coupling constant is chosen such as to obtain resonance widths of $\Gamma_{D,B} = 0.75$ GeV.

With these propagators the elastic $Qq$- and $Q\bar{q}$-scattering matrix elements are calculated and used for evaluation of the pertinent drag and diffusion coefficients for the heavy quarks, using (29) and (30). It turns out that particularly the $s$-channel processes through a $D/B$-meson like resonance provide a large efficiency for heavy-quark diffusion compared to the pQCD cross sections for the same elastic scattering processes. This results in charm-quark equilibration times $\tau_{ceq} = 2$-10 fm/c.

In order to justify the formation of $D$- and $B$-meson like resonances above $T_c$, in \cite{9} a Brueckner-like in-medium $T$-matrix approach has been used for the description of elastic heavy-light-quark scattering in the QGP. After a three-dimensional reduction to a Lippmann-Schwinger equation, including a Breit correction, in-medium heavy-quark potentials from lQCD have been employed as the scattering kernels. As an upper limit of the interaction strength within such an approach, the internal-energy potential,

$$U(r, T) = F(r, T) - T \frac{\partial F(r, T)}{\partial T},$$

has been used, where $F$ is the free-energy potential from the lattice calculation. We take into account also the complete set of $Q\bar{q}$ color states, assuming Casimir scaling of the corresponding potentials,

$$V_8 = -\frac{1}{8} V_1, \quad V_5 = \frac{1}{2} V_1, \quad V_6 = -\frac{1}{4} V_1.$$  \hspace{1cm} (25)

After a partial-wave decomposition the Lippmann-Schwinger equation,

$$T_{a,l}(E; q', q) = V_{a,l}(q', q) + \frac{2}{\pi} \int dk k^2 V_{a,l}(q', k) G_{qq}(E, k)$$

$$\times T_{a,l}(E; k, q)[1 - f_F(\omega_k^Q) - f_F(\omega_{q'}^Q)],$$

for the partial-wave components of each color channel, $a$, has been solved for the $S$- and $P$-wave components. Here, $E$ is the center-of-momentum (CM) energy of the heavy-light quark system, $q$ and $q'$ the momenta of the heavy and light quark, and

$$G_{qq}(E, k) = \frac{1}{E - (\omega_k^Q + i\Sigma_k^{Q}) - (\omega_{q'}^Q + i\Sigma_{q'}^{Q})}$$

the corresponding two-particle propagator in the CM frame. It has been checked that the quasi-particle widths of $\Gamma_{l}^{q,Q} = 2\Sigma_{l}^{q,Q} = 200$ MeV are consistent with a previous similar Brückner calculation \cite{51} for the light quarks and with the heavy-quark self-energies with the $T$-matrix.
solution of (26). The relation with the invariant scattering-matrix elements in (29) is then given by

$$
\sum |M|^2 = \frac{64\pi}{s^2} (s - m_q^2 + m_Q^2)^2 (s - m_Q^2 - m_q^2) \\
\times N_f \sum_a d_a \left( |T_{a,l=0}(s)|^2 + 3|T_{a,k=1}(s)\cos\theta_{cm}|^2 \right). \quad (28)
$$

The relation of elastic heavy-quark-scattering matrix elements with the drag and diffusion coefficients in the Langevin approach is given by integrals of the form

$$
\langle X(p') \rangle = \frac{1}{2\omega_p} \int_{\mathbb{R}^3} \frac{d^3q}{2E(q)(2\pi)^3} \int_{\mathbb{R}^3} \frac{d^3p'}{2E(p')(2\pi)^3} \int_{\mathbb{R}^3} \frac{d^3q'}{2E(q')(2\pi)^3} \frac{1}{\gamma_Q} \sum_{g,q} |M|^2 \\
\times (2\pi)^4 \delta^{(4)}(p + q - p' - q') f_{q,g}(q) X(p'). \quad (29)
$$

Here, the integrations run over the three momenta of the incoming light quark or gluon and the momenta of the outgoing particles. The sum over the matrix element is taken over the spin and color degrees of freedom of both the incoming and outgoing particles; \(\gamma_Q = 6\) is the corresponding spin-color degeneracy factor for the incoming heavy quark, and \(f_{q,g}\) stands for the Boltzmann distribution function for the incoming light quark or gluon. In this notation, the drag and diffusion coefficients are given by

$$
A(p) = \left\langle 1 - \frac{pp'}{p^2} \right\rangle, \\
B_0(p) = \frac{1}{4} \left\langle \frac{p'^2 - (p'p)^2}{p^2} \right\rangle, \\
B_1(p) = \frac{1}{2} \left\langle \frac{(p'p)^2}{p^2} - 2p'p + p^2 \right\rangle. \quad (30)
$$

For both approaches we also include the leading-order perturbative QCD cross sections for elastic gluon heavy-quark scattering \[52\], including a Debye screening mass \(m_{Dg} = gT\) in the gluon propagators, thus taming the \(t\)-channel singularities in the matrix elements. The strong-coupling constant is chosen as \(\alpha_s = g^2/(4\pi) = 0.4\).
The heavy flavor electron spectra at RHIC originate from D- and B-meson decays. These D- and B-meson spectra are obtained from our heavy quark calculations applying a fragmentation or a coalescence mechanism. They are displayed in Fig. 12 for the case of the Peterson fragmentation without using a k-factor, in Fig. 13 for the case of the Peterson fragmentation applying a k-factor of 3 and finally for the case of using a coalescence mechanism (Fig. 14).

These spectra can act as a prediction for future D- and B-meson measurements at RHIC energies. On the one hand they allow for a comparison of our hadronization mechanisms to experimental data and on the other hand for a comparison of the decay to heavy flavor electrons performed using PYTHIA.
