We report new results on identified (anti)proton and charged pion spectra at large transverse momenta ($3<p_T<10$ GeV/$c$) from Cu+Cu collisions at $\sqrt{s_{NN}} = 200$ GeV using the STAR detector at the Relativistic Heavy Ion Collider (RHIC). This study explores the system size dependence of two novel features observed at RHIC with heavy ions: the hadron suppression at high-$p_T$ and the anomalous baryon to meson enhancement at intermediate transverse momenta. Both phenomena could be attributed to the creation of a new form of QCD matter. The results presented here bridge the system size gap between the available $pp$ and $Au+Au$ data, and allow the detailed exploration for the on-set of the novel features. Comparative analysis of all available 200 GeV data indicates that
the system size is a major factor determining both the magnitude of the hadron spectra suppression at large transverse momenta and the relative baryon to meson enhancement.

PACS numbers: 25.75.-q

Differential studies of identified particle production in nucleus-nucleus collisions provide an experimental means to probe the different stages of the collision evolution and explore the properties of the created medium. Spectral measurements at high transverse momenta are of special interest, for the following reasons. In elementary collisions, hard partonic scatterings are known to produce jets of particles originating from the fragmentation of a high-\(p_T\) quark or gluon. The spectral distributions of particles in transverse momentum from such interactions are measured experimentally and are reasonably well understood in terms of Next-to-Leading Order (NLO) pQCD calculations [1]. These hard scatterings occur in heavy-ion collisions as well, but their resulting distributions are found to be modified due to interactions with the medium and the resulting energy loss. Thus, understanding modifications to the high-\(p_T\) particle distributions is an important step towards understanding the partonic energy loss mechanisms within the medium [2].

To study the effects of parton-medium interaction on particle production in heavy-ion collisions we compare the production cross-sections measured in AA to the equivalent measurements in \(pp\) collisions. Following the expectation that the particle production in high-\(p_T\) collisions at high-\(p_T\) is determined by the number of binary nucleon-nucleon inelastic collisions we define the nuclear modification factor, \(R_{AA}\), as the ratio (Eq. (1)) of particle yields measured in AA to the cross-sections measured in \(pp\) collisions scaled by the corresponding number of independent nucleon-nucleon collisions \(N_{bin}^{AA}\). We obtain \(N_{bin}^{AA}\) from a Monte Carlo Glauber model calculation [3]. For the unmodified particle production in AA collisions \(R_{AA}\) is exactly unity, whilst \(R_{AA} < 1\) indicates suppression and \(R_{AA} > 1\) enhancement.

\[
R_{AA} = \frac{\sigma_{NN}^{inc} d^2 N_{AA}/dydp_T}{N_{bin}^{AA} d^2\sigma_{pp}/dydp_T}. \tag{1}
\]

The \(R_{AA}\) measured in \(d+Au\) and peripheral \(Au+Au\) collisions exhibits an enhanced particle production which is believed to occur due to multiple nucleon scatterings within the colliding nuclei. This “initial” state effect is known as the Cronin effect [1, 4, 5]. Meanwhile, in central \(Au+Au\) collisions, \(R_{AA}\) at high-\(p_T\) indicates that the particle production is strongly suppressed (by about a factor of 5) [2, 6]. This “final” state effect has been attributed to the partonic energy loss in an opaque colored medium [7]. However, neither of the two effects is sufficiently understood and both require further experimental and theoretical study. The differential analysis presented here explores the system size effects on parton propagation through the medium to further evaluate the mechanisms of parton/medium interactions.

To provide additional constraints and systematic understanding of the measurements in very light (\(d+Au\)) and heavy (\(Au+Au\)) collision systems we present the key studies at the intermediate (\(Cu+Cu\)) system at the same incident energy (\(\sqrt{s_{NN}} = 200\) GeV), bridging the gap between the two extremes. These measurements may provide quantitative understanding of the partonic energy loss and its system size dependence. In addition, it is expected that the identified particle measurements provide information on color-charge effects within the mechanism of jet quenching. Although experimental discrimination between quark and gluon jet fragmentation on event-by-event basis is difficult, it can be addressed statistically by exclusive analysis of proton (or baryon) and pion (meson) production. We are utilizing the idea that the baryon to meson ratio is found higher in gluon jets compared to quark jets [8]. Identified proton and pion measurements from \(pp\) collisions concur with this picture [1, 9], as well as direct measurements of baryon and meson production in \(Au+Au\) and \(Cu+Cu\) collisions and cannot be explained by cold nuclear matter effects. At present, the preferred baryon over meson production at intermediate \(p_T\) could be described by two very different considerations. The first model assumes coalescence and recombination, which demands a shift of baryon yields to higher momenta relative to meson yields [10]. The second model evokes an interplay of the flow effects in the radially expanding medium with the jet fragmentation [11].

Additionally, systematic studies of identified particle production in \(Cu+Cu\) can shed new light on the anomalous enhancement of baryons with respect to mesons observed at intermediate transverse momenta (2<\(p_T<6\) GeV/c) in \(Au+Au\) collisions. This enhancement is not consistent with the extrapolated values from the measurements in \(pp\) collisions and cannot be explained by cold nuclear matter effects. At present, the preferred baryon over meson production at intermediate \(p_T\) could be described by two very different considerations. The first model assumes coalescence and recombination, which demands a shift of baryon yields to higher momenta relative to meson yields [10]. The second model evokes an interplay of the flow effects in the radially expanding medium with the jet fragmentation [11].

In this paper identified (anti)proton and charged pion spectra are systematically explored with regard to the system size with the smaller \(Cu+Cu\) colliding system at \(\sqrt{s_{NN}}= 200\) GeV. The centrality dependence of high-\(p_T\) hadron production and the \(p_T\) dependence of baryon to meson ratios in \(Cu+Cu\) data are compared to the \(Au+Au\) system as well as to \(pp\) collisions at the same energy. This allows gaining a greater understanding of peripheral collisions. The size of \(Cu\) nuclei is ideally suited to explore the turn-on of the high-\(p_T\) suppression bridging the gap between \(pp\), \(d+Au\) and peripheral \(Au+Au\) data in terms of system size and nuclear matter.

The \(Cu+Cu\) data used in this analysis were recorded by the STAR experiment during Run 5 at RHIC. Here,
the minimum bias trigger was based on the combined signals from the Beam-Beam Counters at forward rapidity (3.3<|η|<5.0) and the Zero-Degree Calorimeters, located at ±18 m from the nominal interaction point [15]. In total, 23 million events comprise this data set. Based on the charged track multiplicity recorded in the Time Projection Chamber (TPC) and Glauber MC model calculations, the data are divided into four centrality bins corresponding to 0-10%, 10-20%, 20-40% and 40-60% of fractional cross-section (σ/σ_{geom}) bins. In order to remove as many background tracks as possible, tracks which intercept the measured collision vertex within 1 cm (distance of closest approach) were retained with a minimum of 25 (out of 45) TPC trajectory points forming each track.

Within the STAR experiment, particle identification at low-\(p_T\) is attained by use of the ionization energy loss (\(dE/dx\)) in the TPC [16]. For low momentum particles, below 1 GeV/c, a clear mass separation is observed allowing the identification of \(\pi^\pm\), \(K^\pm\) and (anti)protons. In the intermediate-\(p_T\) region (1<\(p_T<3\) GeV/c) the TPC is no longer directly usable by itself, as all particles, independent of mass, are minimum ionizing. For the purpose of this paper we identify pions, kaons, protons and anti-protons at higher momenta (\(p_T>3\) GeV/c) on a statistical basis utilizing the relativistic rise of the ionization energy loss in the TPC. For a given slice in transverse momentum, a distinctly non-single-Gaussian shape is observed, discussed in detail in [17], representing the normalized deviations from different energy loss trends of \(\pi\), \(K\) and protons. The quantity used to express the energy loss is a normalized distribution, \(n_\sigma\) defined in Eq. (2), which accounts for the theoretical expectation (\(B_\pi\), known as a Bichsel parameterization) and the resolution of the TPC for pions (\(\sigma_\pi\)).

\[
n_\sigma = \log((dE/dx)/(B_\pi))/\sigma_\pi
\]  

(2)

The resultant distribution in each transverse momentum range is fit with a six-Gaussian function (one per particle-species/charge). The Gaussian widths are considered to be the same, independent of particle type, and single-Gaussian centroids are defined by the theoretical expectations constrained by the identified proton and pion measurements from topologically reconstructed weakly decaying particle yields [17]. Further details of the particle identification technique can be found in Refs. [1, 4].

Raw data yields are corrected for single-track inefficiencies evaluated via Monte-Carlo tracks embedded into real data events. We define single-track efficiency as the fraction of Monte Carlo tracks embedded into real Cu+Cu events that have been reconstructed. The efficiencies are derived for each different event multiplicity bin and particle species. For high-\(p_T\) tracks (\(p_T>2\) GeV/c) in 200 GeV Cu+Cu events, the efficiency is
found to be 85% on average, with a weak (<10%) centrality and \( p_T \) dependence. In the analysis, pion and (anti)proton abundances are extracted from the \( n_\sigma \) distribution using the finely calibrated centroid positions. The derived kaon yields are then smoothed to reduce statistical fluctuations, using a Levy fit. These assumed kaon spectra are then used for a final fit to determine the pion and proton yields. The systematic uncertainties from this procedure, on the spectra, are 2-10% for pions and 5-11% for protons, decreasing smoothly with \( p_T \) in the measured range. An analysis solving simultaneous equations to assumed pion, kaon and (anti)proton distributions (bin counting), derived results that are 5-10% (5-20%) higher for pions (protons). This difference is the dominant systematic uncertainty on particle spectra. An additional systematic error of 5% resultant from the uncertainty in the single-particle efficiency determination is added in quadrature. The total systematic error for pion spectra ranges from 9% (at 3 GeV/c) to 13% (at 10 GeV/c). For protons, the error ranges from 21% (at 3 GeV/c) to 23% (at 6 GeV/c). These uncertainties are similar to the earlier evaluation from Au+Au data analysis [9]. Systematic uncertainties from other possible sources such as the momentum resolution (studied by embedding) and the uncertainty in determination of the centroid position (within the particle identification procedure) are negligible. The corrected transverse momentum spectra for \( \pi^\pm \) and (anti)protons at \( \sqrt{s_{NN}}=200 \) GeV are shown in Fig. 1(a) and (b) respectively. The reach in transverse momentum is limited only by the available statistics. Additional \( p_T \) reach for pion identification is due to a larger separation from the kaon peak (\( \Delta \sigma_{\pi K} \sim 2\sigma, \Delta \sigma_{pK} \sim 1\sigma \)).

Figure 2 shows \( \pi^-/\pi^+ \) and \( \bar{p}/p \) ratios in Cu+Cu data at \( \sqrt{s_{NN}}=200 \) GeV for the four centrality bins. The data show no systematic trends versus centrality within uncertainties, and a weak (if any) decreasing \( \bar{p}/p \) with transverse momentum (as observed in Au+Au collisions [3]). Thus, to improve the statistical uncertainties in the following discussion, data are averaged over particle charge.

The spectral data alone can convey only a limited message. To delve into properties of the resultant data, ratios are taken. The first such ratio is termed the nuclear modification factor \( R_{AA} \), defined in Eq. 1. We find that the pion spectra are suppressed in the most central (head-on) Cu+Cu data at \( \sqrt{s_{NN}}=200 \) GeV (Fig. 2). For the peripheral (glancing) collisions, a small enhancement is observed. To expose the features of the modifications of the hadron spectra in Cu+Cu and Au+Au collisions we study \( R_{AA} \) as a function of the amount of matter participating in the collisions. For both systems \( R_{AA} \) is evaluated within several fractional cross-section bins and as a function of the number of participating nucleons. Figure 3 (a) shows the results of this comparative analysis using the most central 0-12% (open squares) and mid-peripheral 40-60% (open circles) Au+Au data. For the most central events the suppression level is found to be different between the systems. The resultant spectra from Au+Au collisions are more suppressed than in Cu+Cu data. According to the Glauber calculation the mid-central (20-40%) Cu+Cu collisions (closed circles) and mid-peripheral (40-80%) Au+Au data (open circles) have similar numbers of participating nucleons (see Appendix A for details). For this selection of centralities within the two systems we find that numerical values of \( R_{AA} \) agree within the uncertainties. This agreement suggests a correlation of the suppression with the initial volume of the collision system.

In Fig. 3 (b) we present the \( p_T \) averaged \( R_{AA} \) for pions (5<\( p_T <8 \) GeV/c) as a function of the number of participating nucleons calculated for both Cu+Cu and Au+Au collisions. The agreement between Au+Au (open circles) and Cu+Cu (closed circles) is striking and demonstrates that the nuclear modification factor for pions is a smooth function of the number of participating nucleons (independent of the collision system).

Similarly, we explore the systematics of baryon production in Cu+Cu and Au+Au systems by comparing the \( R_{AA} \) for protons and anti-protons. Figure 4 (a) shows the \( R_{AA} \) distributions averaged over \( p \) and \( \bar{p} \) for four centrality bins of Cu+Cu events. The data at hand does not differentiate if collision volume (\( N_{part} \)) or fractional cross-section effects are driving the high-\( p_T \) suppression for baryons due to the larger systematic uncertainties for (anti)proton measurements. Nevertheless, we observe that proton production in the peripheral Cu+Cu events is consistent with binary scaling expectations, and the suppression is setting in as one progresses from the peripheral to central events. An overall similar centrality dependence was observed between the Au+Au and Cu+Cu data at the same energy (see Fig. 4 (b)), albeit Cu+Cu integrated \( R_{AA} \) values seem lower than the respective Au+Au data points. We emphasize that the systematic errors are uncorrelated between the systems, and both measurements are similar within the experimental uncertainties.

The similarity between the different systems at the same number of participants is also evident in other aspects of the data at lower \( p_T \) [13]. The smooth dependence of the nuclear modification factor could be interpreted as a consequence of medium induced energy loss of partons traversing the hot and dense medium. For the smaller systems sizes, either peripheral Au+Au or Cu+Cu data, the path length traversed is smaller (on average) than for the larger system (central Au+Au). As observed in the data, a smaller energy loss is thus predicted [2].

Another dramatic effect observed in Au+Au data is the relative enhancement of protons to pions in the intermediate-\( p_T \) region as compared to \( pp \) and \( e^+ + e^- \) collisions [8] as well as for other baryon to meson ratios [19]. This enhancement is found to be strongly dependent on the centrality of the collision, as illustrated in Fig. 5. The most peripheral A+A data is shown to exhibit little or no enhancement in this ratio, with respect to \( pp \) collisions at the same energy. A similar increasing
FIG. 2: Anti-particle to particle ratios, as a function of transverse momentum for pions (a) and protons (b). Data for the four centrality classes show little centrality dependence. Errors are statistical only.

FIG. 3: (Color online) (a) Nuclear modification factor, $R_{AA}$, for charged pions ($\pi^+ + \pi^-$) in Cu+Cu (filled symbols) and Au+Au (open symbols) collisions at $\sqrt{s_{NN}}=200$ GeV. Error bands are shown for most peripheral and most central Cu+Cu data to represent evolution of the systematic uncertainties for this dataset. Error boxes at $R_{AA}$=1 represent Cu+Cu scale uncertainties due to the number of collisions and from $pp$ spectra normalization. (b) Integrated pion $R_{AA}$ over the range $5<p_T<8$ GeV/c versus $N_{part}$. The bands represent the systematic uncertainty on ratios. An additional scale error due to $pp$ normalization (˜14%) is not shown.

trend of favorable baryon production with centrality is observed in the Cu+Cu collision system. The peak of the enhancement is observed in the region $p_T\sim2$ GeV/c in Au+Au, at a slightly lower transverse momentum than the range measured in this analysis. At higher transverse momenta the enhancement over $pp$ collisions diminishes to the level expected from vacuum fragmentation.

The baryon to meson ratio $(p+\bar{p})/(\pi^++\pi^-)$ in Cu+Cu and Au+Au collisions shows similar trends for an equivalent number of participating nucleons. To further quantify this observation Fig. 5 (b) shows the proton to pion ratio (for hadrons with $3<p_T<4$ GeV/c) measured in
Cu+Cu and Au+Au collisions as a function of $N_{\text{part}}$. We find that this ratio is also sensitive to the initial volume of the collision system and exhibits the same quantitative $N_{\text{part}}$ dependence irrespective of the collision system.

As discussed earlier, it is found that in the kinematic range of our measurements baryons are produced predominantly from gluon fragmentation [20]. It is thus expected that an increase in the baryon to meson ratio in the intermediate- to high-$p_T$ range would be related to gluon sources. To explain the presented data one could consider, for example, that a gluon jet could be more easily propagated through the medium than a...
quark jet, leading to an increase in the number of protons in the intermediate-$p_T$ region. This, however contradicts theoretical predictions where an opposite effect was expected. Alternatively, more gluon jets could be initially produced, or induced (for example, in the radiative energy loss scenario), for the more central data. The latter appears to be the more plausible, as the highest $p_T$ data exhibits little or no enhancement over the $pp$ data, indicating a similar energy loss for gluons and quarks (see Figs. 3 and 4). Alternative approaches to explain the phenomenon observed in the data, have also been developed. For example, the recombination/fragmentation picture of thermal/shower partons has had success at describing this in Au+Au data. Further information on the relative energy loss of quark and gluon jets can be extracted from the data by comparing the nuclear modification factors of proton and pion data (Figs. 3 and 4). At high-$p_T$ (above 5 GeV/$c$), however, the two suppression factors are found to be the same within the systematic uncertainties, suggesting a similar energy loss of quark and gluon jets in Cu+Cu collisions.

In conclusion, new results on high-$p_T$ identified pion and proton spectra are presented for several centrality bins in Cu+Cu collisions at $\sqrt{s_{NN}}=200$ GeV. The data are found to exhibit similar systematic trends over a wide range of transverse momenta as Au+Au collisions at the same energy with a similar number of participants. The suppression pattern observed versus the number of participants in Au+Au data is followed by the Cu+Cu data to a large degree. The participant coverage in these Cu+Cu collisions is in a region where the suppression effects are turning on. A detailed study of the proton to pion ratio reveals similar systematic dependencies to that found in Au+Au data. Specifically, the increase in proton yield at intermediate transverse momenta persists for the much smaller Cu+Cu system.

Further studies have shown similar suppression of protons and pions at high-$p_T$. Within the context of the connection between the detected pions and protons and quark and gluon jets suggested in the introduction, these results indicate similar partonic energy loss for both gluons and quarks. The amount of energy loss suffered by the partons is found to be $N_{\text{part}}$ dependent. Within the experimental uncertainties, the suppression for different collision species is found to be invariant for the same number of participants.

## APPENDIX A: MONTE CARLO GLAUBER MODEL RESULTS FOR THE CENTRALITY BINS USED IN THE PAPER

### TABLE I: Number of participants $N_{\text{part}}$ and number of binary collisions $N_{\text{bin}}$ from the Monte Carlo Glauber model calculations for different centrality bins of minimum bias Cu+Cu collisions at 200 GeV.

| Centrality bin | $N_{\text{part}}$ | $N_{\text{bin}}$ |
|----------------|-------------------|-----------------|
| 0-10%          | 99.0$^{+1.5}_{-1.2}$ | 188.8$^{+15.4}_{-13.4}$ |
| 10-20%         | 74.6$^{+1.3}_{-1.0}$  | 123.6$^{+9.4}_{-8.3}$  |
| 20-40%         | 45.9$^{+0.8}_{-0.6}$  | 62.9$^{+4.2}_{-3.7}$  |
| 40-60%         | 21.5$^{+0.5}_{-0.3}$  | 22.7$^{+1.2}_{-1.1}$  |

### TABLE II: Number of participants $N_{\text{part}}$ and number of binary collisions $N_{\text{bin}}$ from the Monte Carlo Glauber model calculations for different centrality bins of minimum bias Au+Au collisions at 200 GeV.

| Centrality bin | $N_{\text{part}}$ | $N_{\text{bin}}$ |
|----------------|-------------------|-----------------|
| 10-20%         | 234.6$^{+8.3}_{-9.3}$   | 591.3$^{+51.9}_{-59.9}$ |
| 20-40%         | 141.4$^{+9.9}_{-9.5}$   | 294.2$^{+40.6}_{-39.9}$ |
| 40-60%         | 62.4$^{+8.3}_{-10.4}$   | 93.6$^{+17.5}_{-23.4}$ |
| 60-80%         | 20.9$^{+5.1}_{-6.5}$    | 21.2$^{+6.6}_{-7.9}$  |

| Centrality bin | $N_{\text{part}}$ | $N_{\text{bin}}$ |
|----------------|-------------------|-----------------|
| 0-12%          | 315.7$^{+5.6}_{-4.5}$   | 900.3$^{+71.4}_{-63.7}$ |

### TABLE III: Number of participants $N_{\text{part}}$ and number of binary collisions $N_{\text{bin}}$ from the Monte Carlo Glauber model calculations for 200 GeV central triggered Au+Au collisions.

| Centrality bin | $N_{\text{part}}$ | $N_{\text{bin}}$ |
|----------------|-------------------|-----------------|
| 0-12%          | 315.7$^{+5.6}_{-4.5}$   | 900.3$^{+71.4}_{-63.7}$ |
