Abstract

We present a proposal for testing the prediction of non-equilibrium quantum field theory below the Schwinger limit. The proposed experiments should be able to detect a measurable number of gamma rays resulting from the annihilation of pairs in the focal spot of two opposing high intensity laser beams. We discuss the dependence of the expected number of gamma rays with the laser parameters and compare with the estimated background level of gamma hits for realistic laser conditions.

Key words: quantum electrodynamics, non-pertubative limit, pair production, high intensity lasers.
1 Introduction

Current generation of high-repetition and high-intensity lasers as well as $4^{th}$ generation light sources have opened the possibility to experimentally test quantum electrodynamics (QED) at the level where the details of multiple order expansions in the field propagators can be verified with measurable observables. This subcritical field limit is of extreme scientific interest since it will allow progress of the physics research into completely new realms with the generation of novel and unexplored states of matter: electron-positron plasmas and excited vacuum states. Moreover, measured deviations from the predicted QED processes could indicate correction from quantum gravity or Lorentz-violations. These experiments can provide the required benchmark for cosmological vacuum particle production between the Planck and the GUT (Grand Unified Theory) era. In such cases the external field provided by the laser is replaced by the interaction of a massive scalar field with the background space-time, but the governing equations of non-equilibrium quantum field theory (NeqQFT) still hold in the same form.

In this paper we will discuss the theoretical framework implemented to calculate pair production at the subcritical limit and we will solve the governing NeqQFT equations in some idealized, yet representative, case describing the interaction of two high intensity laser beams in vacuum. In the second part of this paper, we will investigate the application of these approaches to a realistic experimental setup. In particular, we will discuss the possibility of observing gamma rays from pair annihilation in the laser focal spot and we will compare this number with the estimated background level. We will use as examples for the experimental configuration both the Gemini laser system, recently commissioned at the Rutherford Appleton Laboratory (UK), and the current generation of petawatt lasers such as the Vulcan laser at the Rutherford Appleton Laboratory. We will also compare optical pair production versus x-ray Free Electron Laser (FEL) sources and discusses the differences among those approaches.

2 Subcritical pair production

Due to its intrinsic simplicity, vacuum pair production is the proposed experiment of choice to test QED in the subcritical field limit. It is well known from basic QED that high energy photon-photon scattering can result in the production of electron-positron pairs. This process and the corresponding reverse interaction of electron-positron annihilation play an important role in determining the overall opacity of the interstellar and intergalactic medium which in turn relates to the correct estimates of the intrinsic luminosity of
stellar objects. At the same time, pair production provides a mean by which large fluxes of positrons could be generated in the vicinity of active galactic nuclei. One of the most exciting results of $\gamma$-ray astronomy has indeed been the detection of the 0.511 MeV emission line from the Galactic center [1]. Massive compact and quasi stellar objects are also source of intense beams of optical and infrared radiation and high-order low-energy multiphoton interactions which result in pair production are also possible. Moreover, processes involving a massive neutral scalar field in a dynamical background (either due to an external semi-classical field or a space-time metric) are applicable to cosmological problems such as vacuum particle production at the Planck time or reheating after GUT scale inflationary expansion [2,3,4]. Another process closely related, and described within the same NeqQFT framework, is the thermal radiation arising from particle production near the event horizon of a black hole, commonly known as Hawking effects [5], as well as the Unruh effect [6], which is seen in uniformly accelerated detectors at relativistic speed. Recently, suggestions have been brought forward that the Unruh effect could be detected with the currently available Gemini laser at the Rutherford Appleton Laboratory [7].

On the theoretical side, subcritical vacuum breakdown is non-perturbative. Solutions exist only for idealized configurations and experimental verification is important for the correct understanding of the process and its relevance to the total interstellar opacity. At the same time this work could provide the first high-density electron-positron plasma to test and simulate a variety of astrophysical environments. With the advent of chirped pulse amplification (CPA) techniques [8] and progresses in x-ray free electron lasers (FELs) [9] it now becomes possible to generate very large numbers of coherent photons (i.e., high electric fields) in both the optical and the x-ray wavelengths. For any astrophysical object we define ?compactness? as the ratio between the total heating divided by its physical size [10]. In our context we are often dealing with high compactness objects, where pairs are primarily created by photon-photon collisions, and the energy loss is negligible as all the pairs remain confined within the laser focal spot. For the production of an electron-positron pair, the center of mass energy of the two photons must exceed $2mc^2$, which precludes the creation of the pair by the collision of two single optical or x-ray photons. In strong electromagnetic fields, however, the interaction is not limited to initial states with two single photons, but allows multiphoton processes [11]

$$N_1(h\omega_1) + N_2(h\omega_2) \rightarrow e^+ + e^-, \quad (1)$$

where $N_1$ and $N_2$ are large integers. Experimental verification of the collision between $\sim 4$ coherent optical photons with one gamma ray photon with energy $\sim 30$ GeV (created by Compton backscatter of another optical photon
against an high energy electron beam) and the corresponding production of electron positron pairs has been demonstrated at the SLAC facility [12,13]. Here, instead, we are interested in the more extreme case of a vacuum breakdown driven by large number of low energy photons $N_1 \sim N_2 = N \gg 1$ and $\omega_1 \sim \omega_2 = \omega \ll m$ (we use, as customary, natural units where $\hbar = c = 1$). This is an example of NeqQFT where quantum mean field approaches have been proposed [2,14,15] but need experimental validation. The basic of these approaches is the so-called quantum Vlasov equation. In spinor QED assuming an external semi-classical electric field, it is possible to show that, for fermions, the particle number operator satisfies an equation of the type [2,15]

$$\frac{df_k(t)}{dt} = \frac{\hat{\Omega}_k(t)\epsilon_\perp(t)}{2\Omega_k(t)\epsilon_\parallel(t)} \times \int_{-\infty}^{t} du \left\{ \frac{\hat{\Omega}_k(u)\epsilon_\perp(u)}{\Omega_k(u)\epsilon_\parallel(u)} [1 - 2f_k(u)] \cos \left[ 2 \int_{u}^{t} d\tau \Omega_k(\tau) \right] \right\},$$  \hspace{1cm} \text{(2)}

which is known as a quantum Vlasov equation, and

$$\Omega_k^2 = m^2 + k_\perp^2 + (k_\parallel - eA)^2,$$  \hspace{1cm} \text{(3)}

with

$$\epsilon_\perp^2 = m^2 + k_\perp^2, \hspace{1cm} \text{(4)}$$

$$\epsilon_\parallel^2 = (k_\parallel - eA)^2, \hspace{1cm} \text{(5)}$$

and $k_\perp (k_\parallel)$ is the momentum perpendicular (parallel) to the linearly polarized electric field $\mathcal{E} = -\dot{A}$ (in the Coulomb gauge). The total electron-positron number per unit volume is then obtained by integrating over all the momenta,

$$\mathcal{N}(t) = 2 \int \frac{d^3k}{(2\pi)^3} f_k(t).$$  \hspace{1cm} \text{(6)}

The quantum Vlasov equation has a non-Markovian character given by the factor $[1 - 2f_k(t)]$ arising from quantum statistics as it takes into account the full history of the distribution function. It simply says that the pair production rate will be affected by the particles already present in the system. However, in the case of weak (subcritical) fields, such an effect can be often neglected [17]. The non-Markovian character is also inherent in the phase oscillations represented by the cosine term. This is related to quantum coherence, resulting from the fact that when the two pairs are created, they are initially fully correlated (i.e., entangled). The time-scale for these quantum coherence effects
to wash out is in the order of \( \tau_{qu} \sim \frac{2\pi}{\Omega_k} \sim \frac{2\pi}{m} \). In order for the statistical description of pair production to be valid, this time must be shorter than the time required to produce the pairs. This, for small \( k \), can be estimated from Eq. (2) to be \[ 14 \]

\[ \tau_{cl} \sim \left[ \frac{\Omega_k(t)\epsilon_1(t)}{\Omega_k(t)\epsilon_2(t)} \right]^{-1} \sim \frac{m}{\epsilon E}. \]  

(7)

In the semi-classical case we also need to assume that the external field remains approximately constant during particle generation, that is \( \tau_{cl} < \tau_{pl} \) \[ 14 \], where \( \tau_{pl} \) is the characteristic time associated to collective plasma fluctuations: \( \tau_{pl} = \frac{2\pi}{\omega_{pl}} = \frac{2\pi(m/e^2n_{av})^{1/2}}{1} \) with \( n_{av} \) the average pair density.

Equation (6) is just a formal solution, and a few words are necessary in order to correctly interpret its meaning. This point has been discussed in the literature \[ 2,3 \], and it stems from the fact that the number of pairs does not commute with the Hamiltonian (indeed it is not a constant of motion). This follows directly from the uncertainty principle. If we have \( N_{ep} \) pairs, the uncertainty relation reads as

\[ \Delta E\Delta t = \Delta(N_{ep}m)\Delta t \sim 1, \]  

(8)

and the uncertainty in the particle number is \( \Delta N_{ep} \sim 1/m\Delta t \). This implies that the particle number is indeed a well defined quantity at asymptotic times \((\Delta t \to \infty)\) or for very massive (classical) particles. On the other hand, this relation applies only for a system where particle production during the time interval under consideration is negligible. In the more general case, we need to assume that particles will be produced within the considered time interval. We thus obtain

\[ \Delta N_{ep} \sim \frac{1}{m\Delta t} + \left| \frac{dN_{ep}}{dt} \right| \Delta t, \]  

(9)

which, letting \( dN_{ep}/dt \sim N_{ep}/\tau_{cl} \), is minimized for

\[ \Delta t = \tau_{mi} = \frac{1}{(m|dN_{ep}/dt|)^{1/2}} \sim 1/(N_{ep}\epsilon E)^{1/2}. \]  

(10)

The particle number is a well defined quantity only if the change in the number of particles is small within the time we are considering. If not, we need to resort to higher order approximations. This renormalization technique is referred to as adiabatic regularization \[ 2,14,16 \]. We note that \( \Delta N_{ep} \) cannot be made arbitrarily small, and it is minimized for \( \Delta N_{ep} = (2/m^{1/2})|dN_{ep}/dt|^{1/2} \sim \)
2(N_{ep}e\mathcal{E})^{1/2}/m. In summary, the quantum Vlasov equation represents a physical observable (the number of electron positron pairs) only if the hierarchy of times $\tau_{mi} \lesssim \tau_{cl}$ and $\tau_{qu} < \tau_{cl} < \tau_{pl}$ is satisfied.

We should note that the NeqQFT framework is not the only one been implemented in the calculation of subcritical pair production, and at present a large amount of theoretical work has appeared \cite{16,19,20,21,22,23,24,25}. While the various approaches seem to converge for large electric fields \cite{17}, some discrepancies in the predicted pair number are seen in the subcritical regime. On the other hand, recent work seems to demonstrate that despite theoretical techniques being very different, they are effectively equivalent solution of the same problem, with the differences arising only from the details of the numerical methods \cite{26}. Still remains the fact that the precise details of the vacuum breakdown mechanisms in full spatial and temporal resolution are not yet fully understood despite the pioneering work of Schwinger \cite{27}. Techniques based on the worldline path integral \cite{28,29} as well as calculation of the tunneling probabilities of virtual pairs from the Dirac sea \cite{30,31} have been successful in determining the pair production in simplified non-uniform field configurations. However, experiments in supercritical fields (i.e., in the Coulomb field of an ion) have shown contradicting results and the question is still open on whether the Dirac equation is applicable in these scenarios \cite{25} — see also discussions on the Klein paradox \cite{32} — and the necessity to use a multi-body second quantization formalism (as in the NeqQFT approaches) becomes clear. In simpler terms, as particles are created, their associated electric field adds to the external field, which then feeds back to the production of the next pair.

3 Solution of the quantum Vlasov equation for idealized fields

Several attempts have been made to solve the quantum Vlasov equation in cosmological regimes \cite{2,3,4}. More recently, attention has been drawn to the fact that the new generation of laser and FEL facilities has now reached electric field intensities where the particle production could have observable effects. In the simplest case of a time invariant, spatially homogeneous electric field, the solution is well known. This was originally derived by Schwinger \cite{2,27} and found that the pair number is exponentially suppressed:

$$\mathcal{N}_{\text{Schwinger}} \propto \exp \left(-\pi \frac{m^2}{e\mathcal{E}}\right) = \exp \left(-\pi \frac{\mathcal{E}_c}{\mathcal{E}}\right),$$

(11)

where $\mathcal{E}_c = m^2/e = 1.3 \times 10^{18}$ V/m is the Schwinger field. Since the critical field corresponds to the electric field such that its work on two electron charges separated by a Compton wavelength equals their rest mass, to reach a
sizeable rate of pair production we need to have $\mathcal{E} \gtrsim \mathcal{E}_c$. On the other hand, the subcritical field regime is defined by the weak field condition $\mathcal{E} \ll \mathcal{E}_c$, implying a negligible number of pairs being generated. Equation (11) is only valid for static fields. In case of dynamically variable electric fields, the pair production problem can be understood as a tunneling with an oscillating barrier. This enhances the probability of generation of pairs since the average barrier seen by the virtual pair is lower.

A clear advantage of the quantum Vlasov approach is that it can be used to model the full temporal dependence of the particle number for any time $t \gtrsim \tau_{cl}$. A solution of Equation (2) for a sinusoidal, spatially homogeneous, laser field has been recently proposed [24]. In this paper, we will consider instead a different temporal dependence of a spatially uniform field at the laser focus of two counter propagating laser beams:

$$\mathcal{E}(t) = \mathcal{E}_0 \sinh^2(\nu t), \quad (12)$$

for which the Dirac equation is exactly solvable and analytical approximations are easily obtained. If we assume that the pair production is modest, i.e., $f_k \ll 1$, and $\mathcal{E}_0 \ll \mathcal{E}_c$, then $[33]$

$$\mathcal{N}(t) = \frac{1}{2(2\pi)^3} \int d^3k \epsilon^2 \left| \int d\Omega_k \frac{e\mathcal{E}(u)}{\Omega^4_k(u)} \exp \left( 2i \int^t_{-\infty} d\tau \Omega_k(\tau) \right) \right|^2. \quad (13)$$

Under the condition $e\mathcal{E}_0/m\nu \ll 1$, which implies a semi-classical motion of the charges in the electric field, the pair number can be further simplified to $[33]$

$$\mathcal{N}(t) \sim \frac{1}{2(2\pi)^3} \int d^3k \frac{\epsilon^2}{\Omega^4_k(t)} \left| \int_{-\infty}^t du e\mathcal{E}(u) e^{2i\Omega_k u} \right|^2. \quad (14)$$

Using the field (12), the asymptotic (residual) pair number density becomes

$$n_r = \mathcal{N}(t = \infty) = \frac{(e\mathcal{E}_0)^2}{2(2\pi)^3} \int d^3k \frac{\epsilon^2}{\Omega^4_k} \left| \frac{2\pi \text{csch} (\pi \Omega_k/\nu)}{\nu^2} \right|^2 \sim \frac{4}{3} \frac{(e\mathcal{E}_0)^2}{m} \left( \frac{m}{\nu} \right)^4 e^{-2\pi m/\nu}, \quad (15)$$

where we have assumed $\nu \ll m$, and $\epsilon \sim \Omega_k$ (which is valid for weak fields). Moreover, we have taken $\Omega_k \sim m$ for $k \lesssim m$ and $\Omega_k \sim k$ for $k \gtrsim m$. We see that in this case, pair production is exponentially suppressed for subcritical fields. The exponential term $e^{-2\pi m/\nu}$ is indeed equivalent to what obtained with other
techniques [30, 31]. This confirms the fact that, even for oscillating fields, a significant number of pairs can persist only for fields close to the Schwinger limit. The specific functional form for the residual density is dependent on the exact time variation of the electric field, and different results are obtained for sinusoidal fields \( E(t) = E_0 \sin(\nu t) \) [24, 33]. In the latter case, the residual density after one oscillation period is \( n_r \sim (eE_0\nu)^2/m^3 \), which is again negligible in the subcritical regime.

While the residual density is exponentially suppressed at asymptotic times for the idealized field of Eq. (12), the pair density at finite times is significantly larger. The average pair density during the field excitation can be approximated as

\[
n_{av} \sim \frac{N(t = 0)}{2} = \frac{1}{4(2\pi)^3} \int d^3k \frac{\epsilon^2}{\Omega_k^4} \left[ \int_{-\infty}^{0} du eE(u) e^{i\Omega_k u} \right]^2
\]

\[
\sim \frac{(eE_0)^2}{4(2\pi)^3} \int d^3k \frac{\epsilon^2}{\Omega_k^4} \left| \frac{1}{2i\Omega_k} \right|^2
\]

\[
\sim \frac{1}{24\pi^2} \frac{(eE_0)^2}{m}.
\]

Differently from the residual number, the average pair density is not exponentially suppressed. Moreover, calculation assuming a sinusoidal field showed the same functional dependence apart from a numerical prefactor of order unity [24, 33]. This may indicate that the average pair density is not too sensitive on the details of the field fluctuations.

Until now we have considered spatially homogeneous fields. Real fields, however, are not spatially uniform and variations are expected to occur on some macroscopic scale \( \Lambda \). These effects are more easily estimated within the semi-classical tunneling probability calculation [30, 31]. Since in a spatially inhomogeneous field pairs are initially produced at the maximum of the field, if they move away from this point and the field drops too sharply, they may not gain enough energy to cross the barrier and become real particles. Thus, opposite to the case of time varying fields, spatial gradients tend to suppress pair production. It can be shown that in the subcritical regime this effect introduces a correction to the pair production number of the order [30, 31]

\[
C \sim 1 - \frac{5}{4} \left( \frac{m}{eE_0\Lambda} \right)^2,
\]

where \( m/eE_0\Lambda \ll 1 \).
4 Observable effects from pair production

As we have discussed in the previous section, in the subcritical regime, pair production at asymptotic times is always exponentially suppressed, meaning that no residual pairs remains after the laser. On the other hand, there is a significant number of pairs during the time the electric field is switched on. Assuming that the laser has wavelength $\lambda$, then the estimated total number of electron-positron pairs in the laser spot volume $V \sim s^2 \lambda$ (where $s \gg \lambda$ is the laser spot diameter) is given by

$$N_{ep} = V n_{av} \mathcal{C} \simeq \frac{s^2 \lambda}{24 \pi^2} \left( \frac{e \mathcal{E}_0}{m} \right)^2 \left[ 1 - \frac{5}{4} \left( \frac{m}{e \mathcal{E}_0 s} \right)^2 \right],$$

(18)

where the scale of spatial inhomogeneities is given by the spot size ($\Lambda \sim s$).

Such number of electron-positron pairs has a clear observable effect, namely the generation of gamma rays due to pair annihilation. If during the laser pulse the particle number is a well defined physical quantity, then collision between those particles are indeed possible. Since the pair number scales with the laser wavelength (i.e., the interaction volume at the focal spot), it shows that optical lasers have some advantage over x-ray FELs. On the other hand, for very intense FELs we could have the opposite scenario where the spot volume is too small to generate a sizeable number of pairs during the evolution of the laser pulse, but the field intensity is large enough that a finite number of pairs remains at asymptotic times. Those pairs may lead to accumulation effects (i.e., interacting with the external field) and induce spontaneous pair production over several laser cycles [34], which is a consequence of the non-Markovian character of the quantum Vlasov equation. While the quantum Vlasov equation is a collisionless equation, if collisions are a small perturbation, then the momentum distribution of the pairs is unaltered and the resultant number of gamma rays is obtained by multiplying their distribution functions by the annihilation cross section integrating over all the momenta of the pairs [24]. However, since we want to explore the scaling of the laser parameters with the observable number of gamma rays, we will follow here an equivalent analytical approximation. The ratio of electron-positron collisions producing gamma ray annihilation is [35]

$$R = \sigma_T \left( \frac{\mathcal{E}_c}{\mathcal{E}_0} \right) \nu^2,$$

(19)

where $\sigma_T$ is the Thomson cross section, which applies at low energies compared to the rest mass, as in our case. The model is applicable if collective plasma phenomena take places on a scale shorter than the laser cycle, i.e., $\tau_{pl} < 2\pi/\nu$, thus allowing sufficient time for the particle to interact [14,36]. This also shows
that as the laser field decreases, annihilation processes becomes more probable. Physically, this means that pairs produced with smaller momenta are more likely to result in a collision event. The number of gamma rays emitted is thus

$$\tilde{N}^{\gamma\gamma} \simeq N_{ep} R = \frac{\sigma_T s^2 \lambda \nu^2}{24\pi^2} \left( \frac{e^2 \mathcal{E}_c \mathcal{E}_0}{m} \right) \left[ 1 - \frac{5}{4} \left( \frac{m}{e \mathcal{E}_0 s} \right)^2 \right]$$

$$\simeq \frac{\sigma_T s^2}{3\lambda} \left( \frac{e^2 \mathcal{E}_c \mathcal{E}_0}{m} \right) \left[ 1 - \frac{5}{4} \left( \frac{m}{e \mathcal{E}_0 s} \right)^2 \right], \quad (20)$$

where we have used the fact that \( \nu \sim 2\pi/\lambda \) (which is exact for a sinusoidal wave). While the treatment presented here is far from being complete, the values obtained with this approach are in agreement with the predicted number of gamma rays calculated by full integration of the pair distribution function from the quantum Vlasov equation \cite{24}. Both approaches are, however, not self consistent, and a complete analysis will require the addition of a collisional sink term in the quantum Vlasov equation \cite{15,37}, which must then be coupled to the gamma ray production rate. Only in this way the full effects of entanglement and quantum statistics could be properly accounted for.

In order to get a realistic value for the expected number of gamma rays, we also need to account for the fact that counter propagating beam geometries are experimentally difficult to realize (see, however Ref. \cite{38} for a suggested counter-propagating beam geometry). If \( \theta \) is the angle between the two beams, then this introduces a geometrical correction \( (1 - \cos \theta)/2 \). Moreover, if the laser beam has a pulse duration \( \tau_L \), then gamma ray annihilation events will occur \( \tau_L \nu/2\pi \) times during the laser shot.

Bringing back the factors of \( c \) and \( \hbar \), the total number of expected \( \gamma\gamma \) events during a laser pulse is then

$$N^{\gamma\gamma} \simeq \frac{(1 - \cos \theta) \sigma_T m c^3 s^2 \tau_L c \mathcal{E}_0}{3(hc^2)^2} \left[ 1 - \frac{5}{4} \left( \frac{mc^2}{e \mathcal{E}_0 s} \right)^2 \right], \quad (21)$$

with the electric field is expressed in terms of the laser intensity, \( I_0 \), as \( \mathcal{E}_0 = (2\mu_0 c I_0)^{1/2} \) (in SI units).

### 5 Photometric

In this section we compare expected number of \( \gamma \) photons from pair annihilation with respect to background noises. As shown in Table\[\text{1}\] we expect \( \sim 0.6 \) annihilation events per laser shot, corresponding to \( \sim 10000 \)-events in a 10 hr
experiment using the Astra Gemini laser available at the Rutherford Appleton Laboratory. In a full experimental week, this corresponds to $5 \times 10^4$ annihilation events producing two gamma ray photons. Coincidence measurements will be performed with high sensitivity large area NaI gamma ray detectors covering a solid angle of $\sim 2\pi$, with an absolute conversion efficiency $> 0.08$\cite{39}. We can estimate a total detection of $\sim 2 \times 10^3$ events. In situ measurements to assess the background level within the laser area have observed 2060 positron events in 10 hours, equivalent to 0.05 counts/s. Since the NaI detectors can be gated with integration time $\sim 1$~µs, the background level of cosmic ray hits can be minimized to $\sim 0$. Any sporadic background event could be further eliminated with a coupled anti-coincidence detector.

The major source of noise in these experiments arises from bremsstrahlung photons emitted by electrons stripped from the residual gas in the laser focal spot. Since relativistic electrons will be produced at laser intensities $I_0 \gtrsim 10^{19}$ W/cm$^2$, this corresponds to a much larger volume than the laser focal spot. For the Astra Gemini laser, at pressures $\sim 10^{-6}$ mbar, we expect up to $10^4$ electrons being ejected by the residual atoms (mostly hydrocarbons and oxygen). If these electrons are all emitted in a narrow cone, the probability that each one of them collides with a residual atom before reaching the chamber walls ($\sim 1$~m path length) is less than $10^{-4}$. During such a collision a gamma ray photon is emitted, corresponding to $< 0.04$ events detected per laser shot (0.002 counts/s). If the gamma detectors are all placed within 1 m from the laser interaction point and outside the stripped electrons path, no additional gamma ray event will be recorded, as electrons hitting the chamber walls will emit photons in the forward direction away from the detector units (as well as excluded by coincidence detection).

We notice from Table 1 that the error in the number of pairs is substantially larger than 1. This implies that the (rest) energy of those pairs is undetermined with an error (for the Gemini laser) of 1.3 MeV. Alternatively, this results can be interpreted in the sense that only a fraction of pairs has materialized on the mass shell, but the rest are still virtual. However, since the detection efficiency of scintillators remains the same over the $\sim 1$ MeV range (centered at 0.511 MeV)\cite{40}, we would expect that at worst a count rate is reduced by a factor of 2, to 0.025 counts/s (1030 positron events in 10 hours), but still significantly above background.
Table 1
Operation parameters for current laser systems and expected γγ yield. A beam crossing angle of θ = 135° has been assumed. The Astra Gemini and the Vulcan PW systems are both located at the Rutherford Appleton Laboratory.

|                          | Astra Gemini | Vulcan PW |
|--------------------------|--------------|-----------|

6 Conclusions

We have presented a proposal to test subcritical pair production with high intensity lasers. Using the theoretical framework of NeqQFT we have shown that the residual pair density after the laser shot is exponentially suppressed, and the number of pairs remaining is negligible. However, for realistic laser conditions, there is a significant number of pairs during the field evolution and the observable effect of such pairs is the production of co-incident gamma rays. We have estimated for the Astra Gemini laser facility at the Rutherford Appleton Laboratory more than 10⁴ annihilation events during an experimental day. Photometric analysis has shown that this number of events will be detectable with current instrumentation. We are proposing an experimental platform that could test, for the first time, NeqQFT models which are relevant to astrophysical and cosmological processes, and, at the same time, resolve issues with the current approximation schemes of non-perturbative QED.
This work was supported in part by the Science and Technology Facilities Council of the United Kingdom, by Department of Energy, Office of Nuclear Physics, contract no. DE-AC02-06CH11357 and by the Polish Ministry of Science and Higher Education under grant no. N N 202 0953 33. D.B.B., A.V.P., G.R. and S.A.S. are grateful for support from the Helmholtz Association for their participation at the Summer School on Dense Matter in Heavy-Ion Collisions and Astrophysics in Dubna, July 14-26, 2008, where this project has been started. D.B.B. thanks D. Habs and G. Mourou for enlightening discussions and encouragement during the ELI workshops, in particular the one at Frauenwörth, October 2008. G.G. would also like to thank T. Heinzi for useful discussions about the manuscript.
