(Dated: May 5, 2009)

Edge channels play a crucial role for electron transport in two dimensional electron gas under magnetic field. It is usually thought that ballistic transport along edges occurs only in the quantum regime with low filling factors. We show that a microwave field can stabilize edge trajectories even in the semiclassical regime leading to a vanishing longitudinal resistance. This mechanism gives a clear physical interpretation for observed zero-resistance states.

PACS numbers: 73.40.-c, 05.45.-a, 72.20.My

The experimental observation of microwave induced zero-resistance states (ZRS) in high mobility two dimensional electron gas (2DEG)\(^{[1,2]}\) attracted significant experimental and theoretical interest. Several theoretical explanations have been proposed so far, which rely on scattering mechanisms inside the bulk of 2DEG. The “displacement” mechanism originates from the effect of microwaves on disorder elastic scattering in the sample\(^{[3,4,5,6]}\), while the “inelastic” mechanism involves inelastic processes that lead to a modified out-of equilibrium distribution function\(^{[7,8]}\). Even if these theories reproduce certain experimental features we believe that the physical origin of ZRS is still not captured. Indeed several arguments can challenge these approaches. The above theories naturally generate negative resistance states but one has to rely on an uncontrolled out of equilibrium compensation of all currents to produce ZRS as observed in experiments\(^{[1,2]}\). Also ZRS is observed in very clean samples, therefore in the bulk an electron moves like an oscillator where selection rules allow transitions only between nearby oscillator states. Hence resonant transitions are possible only at cyclotron resonance where the ratio between microwave frequency \(\omega\) and cyclotron frequency \(\omega_c\) is unity. However experiments show that the onset of ZRS occurs also for high \(j = \omega/\omega_c\) approximately at \(j = 1 + 1/4, 2 + 1/4, \ldots\). High \(j\) resonances could appear due to nonlinear effects, however the microwave fields are relatively weak giving a ratio \(\epsilon\) between oscillating component of electron velocity and Fermi velocity \(v_F\) of the order of few percents. Therefore the appearance of high \(j\) ZRS in “displacement” models with weak disorder seems problematic. In the “inelastic” models one assumes that 2DEG evolves in a far from equilibrium state due to small energy relaxation rates. However since the microwave frequency is high compared to the elastic rate 2DEG has mainly imaginary high frequency conductivity and should not significantly absorb microwave power. This can be seen very clearly in\(^{[1]}\) where the amplitude of the Shubnikov-de Haas oscillations is not changed by the presence of microwave radiation even when power is strong enough to generate ZRS. Hence it seems unlikely that 2DEG actually reaches the out of equilibrium states needed for the “inelastic” theories.

In order to develop a theory for ZRS we note that they occur when the mean free path \(l_c\) is much larger than the cyclotron radius \(r_c = v_F/\omega_c\). In usual 2DEG samples with lower mobilities this regime corresponds to strong magnetic fields and quantum Hall effect. In this case it is known that propagation along sample edges is ballistic and plays a crucial role in magnetotransport. It leads to quantization of the Hall resistance \(R_{xy}\) and to the disappearance of four terminal resistance \(R_{xx}\) strikingly similar to ZRS\(^{[3]}\). This occurs at low filling factors \(\nu\) when a gap forms in the 2DEG density of states due to discreetness of Landau levels. In contrast to that ZRS appear at \(\nu \simeq 50\) where Landau levels are smeared out by disorder. Even in this semiclassical regime, edge trajectories are still important for transport. Guiding along sample edges can lead to a significant decrease of \(R_{xx}\) with magnetic fields giving a negative magnetoresistance and singularities in \(R_{xy}\)\(^{[10,11]}\) (note that negative magnetoresistance is also observed in ZRS samples\(^{[1,2]}\)\(^{[12]}\)). This behaviour can be understood theoretically from the transmission probability \(T\) between voltage probes in a Hall bar geometry\(^{[11]}\). The drop in \(R_{xx}\) is linked to increased \(T\), but transmission remains smaller than unity due to disorder and \(R_{xx}\) remains finite. Recently this model was extended to understand experimental deviations from Onsager reciprocity relations in samples under microwave driving\(^{[13]}\). But the impact of microwaves on stability of edge channels was never considered before.

In this Letter we show that microwave radiation can stabilize guiding along sample edges leading to a ballistic transport regime with vanishing \(R_{xx}\) and transmission exponentially close to unity. It was established experimentally that edge channels are very sensitive to irradiation\(^{[14]}\) and recent contact-less measurements in the ZRS regime did not show a significant drop of \(R_{xx}\)\(^{[15]}\) that supports our edge transport mechanism for ZRS. Our model also relies on the fact that scattering occur on small angles in 2DEG\(^{[1,10]}\). This contrasts with
where $\delta v = 4 \epsilon / \omega_c$ and the resonance separatrix width $\delta v = 4 \sqrt{\epsilon / \omega_c}$. The energy barrier of the resonance is given by $E_r = (\delta v)^2 / 2 = \omega_c / \omega$.

In presence of weak dissipation the center of resonance acts as an attractor for trajectories inside the resonance. The presence of small angle scattering leads to a broadening of the attractor but trajectories are still trapped inside. If the center is located near $v_y = 0$ particles are easily kicked out from the edge, transmission $T$ drops and $R_{xx}$ increases. On the other hand, if the resonance width $\delta v$ does not touch $v_y = 0$ then orbits trapped inside propagate ballistically with $T \to 1$ and $R_{xx} \to 0$. The trapping is confirmed in Figs. 1e,f for both models at $\omega / \omega_c = 9/4$ with propagating trajectories concentrated inside the resonance, whereas for $\omega / \omega_c = 2$ in Fig. 1a the region inside the resonance does not propagate (propagating orbits concentrate on the unstable separatrix and their number is much smaller).

FIG. 1: (Color online) a) Examples of electron trajectories along sample edge for several values of $j = \omega / \omega_c$ and $y$-polarized field $\epsilon$. b) Poincaré section of (1) for $\omega / \omega_c = 9/4$ at $y$-polarized $\epsilon = 0.02$. c) Poincaré section in the same region for the Chirikov standard map (2) giving approximate description of dynamics in b). In a,b,c) dissipation and impurity scattering angle are zero. d,e,f) Density of propagating particles on the Poincaré section in presence of noise and dissipation (red/gray for maximum and blue/black for zero), black points show trajectories without noise and dissipation. For $\omega / \omega_c = 2$ microwave repels particles from the edge (d), while for $\omega / \omega_c = 9/4$ particles trapped inside the nonlinear resonance (e,f). Here $\gamma_0 = 10^{-3}$ (e), $\gamma_c = 10^{-2}$ (d,f) and $\alpha = 5 \times 10^{-3}$.

other ZRS models which do not rely on specific physical properties of 2DEG.

Since filling factors are large we study classical dynamics of an electron at the Fermi surface propagating along a sample edge modeled as a specular wall. The motion is described by Newton equations:

$$d\mathbf{v}/dt = \omega_c \times \mathbf{v} + \epsilon \cos \omega t - \gamma(v)\mathbf{v} + I_{wall} + I_S$$

(1)

where $\epsilon = eE / (m\omega_c)$ describes microwave driving field $E$, velocity is measured in units of Fermi velocity $v_F$, and $\gamma(v) = \gamma_0 (|v|^2 - 1)$ describes relaxation processes to the Fermi surface. The last two terms account for elastic collisions with the wall and small angle scattering. Disorder scattering is modeled as random rotations of $\mathbf{v}$ by small angles in the interval $\pm \alpha$ with Poissonian distribution over microwave period. Examples of electron dynamics along the sample edge for $\gamma_0 = 0$ and $\alpha = 0$ are shown in Fig. 1a. They show that even a weak field $\epsilon = 0.1$ has strong impact on dynamics along the edge. A more direct understanding of the dynamics can be obtained from the Poincaré sections constructed for the microwave field phase $\phi = \omega t (\mod 2\pi)$ and the velocity component $v_y > 0$ at the moment of collision with the wall. The system has two and half degrees of freedom and therefore the curves on the section are only approximately invariant (Fig. 1b). The main feature of this figure is the appearance of a nonlinear resonance. We assume for simplicity that 2DEG is not at cyclotron resonance and polarization is mainly along $y$ axis. Since Eq. (1) is linear outside the wall, one can go to the oscillating frame where electron moves on a circular orbit while the wall oscillates in $y$ with velocity $\epsilon \sin \omega t$. Hence collisions change $v_y$ by twice the wall velocity. For small collision angles the time between collisions is $\Delta t = 2(\pi - v_y) / \omega_c$. This yields an approximate dynamics description in terms of the Chirikov standard map [17]:

$$\dot{v}_y = v_y + 2\epsilon \sin \phi + I_{cc}, \quad \dot{\phi} = \phi + 2(\pi - v_y) / \omega_c$$

(2)

The term $I_{cc} = -\gamma \epsilon v_y + \alpha_n$ describes dissipation and noise, bars denote values after map iteration ($-\alpha < \alpha_n < \alpha$). Damping from electron-phonon and electron-electron collisions contribute to $\gamma$. The Poincaré sections for Eqs. (1,2) are compared in Figs. 1b,c showing that the Chirikov standard map gives a good description for edge dynamics under microwave driving. A phase shift by $2\pi$ does not change the behavior of map (2) and hence the phase space structure is periodic in $j = \omega / \omega_c$ with period unity which naturally yields high harmonics. The resonance is centered at $v_y = \pi(1 - \epsilon \omega / \omega_c)$ where $m$ is the integer part of $\omega / \omega_c$. The chaos parameter of the map is $K = 4\epsilon \omega / \omega_c$ and the resonance separatrix width $\delta v_y = 4 \sqrt{\epsilon \omega_c / \omega}$. The energy barrier of the resonance is given by $E_r = (\delta v_y)^2 / 2 = 8\epsilon \omega_c / \omega$.

In presence of weak dissipation the center of resonance acts as an attractor for trajectories inside the resonance. The presence of small angle scattering leads to a broadening of the attractor but trajectories are still trapped inside. If the center is located near $v_y = 0$ particles are easily kicked out from the edge, transmission $T$ drops and $R_{xx}$ increases. On the other hand, if the resonance width $\delta v$ does not touch $v_y = 0$ then orbits trapped inside propagate ballistically with $T \to 1$ and $R_{xx} \to 0$. The trapping is confirmed in Figs. 1e,f for both models at $\omega / \omega_c = 9/4$ with propagating trajectories concentrated inside the resonance, whereas for $\omega / \omega_c = 2$ in Fig. 1d the region inside the resonance does not propagate (propagating orbits concentrate on the unstable separatrix and their number is much smaller).

In order to compare our theory with experiment we calculate the transmission $T$ for model (1). An ensemble
of $N = 5000$ particles is thrown on the wall at $x = 0$ with random velocity angle. They propagate in positive $x$ direction but due to noise some trajectories detach from the wall, we consider that a particle is lost in the bulk when it does not collide with the wall for time $20\pi/\omega_c$. These particles do not contribute to transmission which is defined as the fraction of particles that reaches $x = 250v_F/\omega$, that can be viewed as a distance between contacts. For $l_c \gg r_c$ the billiard model of a Hall bar [11, 13] gives $R_{xx} \propto 1 - T$ and a deviation from the classical Hall conductance $\Delta R_{xy} = R_{xy} - B/ne \propto -(1 - T)$. The data in Fig. 2 show calculated $1 - T$ and experimental $R_{xx}$ and $\Delta R_{xy}$ [2]. One can see a good agreement between results of model (1) and experimental data. Both show $R_{xx}$ peaks at integer $j$ and zeros around $j = 5/4, 9/4$. We also reproduce peaks and dips for “fractional” ZRS around $j = 3/2, 1/2$ [18]. Our specular wall potential is specially suited for the cleaved samples from [2] where edges should follow crystallographic directions but peak positions can be shifted for other edge potentials. We also note that the possibility to observe ZRS on $\Delta R_{xy}$ was discussed in [19, 20]. Finally our data show weak dependence on polarization axis which supports the Chirikov standard map model.

Model [2] is more accessible to analytical analysis and numerical simulations. In this model a particle is considered lost in the bulk as soon as $v_y < 0$. The displacement along the edge between collisions is $\delta x = 2v_y/\omega_c$ and an effective “diffusion” along the edge is defined as $D_x(\epsilon) = (\Delta x)^2/\Delta t$ where $\Delta x$ is a total displacement along the edge during the computation time $\Delta t \sim 10^3/\omega$. In numerical simulations $D_x$ is averaged over $10^4$ particles homogeneously distributed in phase space. We then assume that $R_{xx} \propto 1/D_x$ and present the dependence of the dimensionless ratio $R_{xx}/R_{xx}(\epsilon = 0)$ on $\omega/\omega_c$. in Fig. 3. The computation of transmission $T$ (shown in Fig. 3 inset) gives similar results but is less convenient for numerical analysis. The dependence on $j = \omega/\omega_c$ is similar to those shown in Fig. 2. Both peaks and dips grow with the increase of microwave field $\epsilon$.

The dependence on $\epsilon$ can be understood from the following arguments. Due to noise a typical spread square width in velocity angle during the relaxation time $1/\gamma_c$ is $D_x = \alpha^2/\gamma_c$. The resonance square width is $(\delta v_y)^2 = 16\omega_c/\omega$ and therefore the probability to escape from the resonance is

$$W \sim \exp(-{(\delta v_y)^2}/D_x) \sim \exp(-A\omega_c/(D_x\omega))$$  (3)

Edge transport is ballistic for exponentially small $W$ and $R_{xx}/R_{xx}(0) \sim 1 - T \sim W$. The above estimate gives the numerical coefficient $A = 16$ while numerical data presented in Fig. 4 for model [2] give $A \approx 12$, and confirm dependence Eq. (4) on all model parameters. It holds when edge transport is stabilized by the presence of the nonlinear resonance which corresponds to regions around $j = 5/4, 9/4$. Deviations appear when the parameter $K = 4\epsilon\omega/\omega_c$ approaches the chaos border $K \approx 1$ and trapping is weakened by chaos. The numerical data for model [1] based on transmission computation confirm the scaling dependence $\log R_{xx}/R_{xx}(0) \propto -\omega_c/\epsilon/\omega$ as shown in Fig. 4. This dependence holds also for other models of dissipation in Eqs. (12). It is consistent with
the power dependence measured in [1]. A detailed analysis of the power dependence may be complicated due to heating and out of equilibrium effects at strong power, but the global exponential decay of $R_{xx}$ with power was confirmed in [11].

The billiard model used in our studies focuses on dynamics of an electron on the Fermi surface which corresponds to a zero temperature limit. In order to include the effect of temperature $T_e$ one needs to account for the thermal smearing of the electrons around the Fermi surface. The relaxation rate to the Fermi surface that we introduced in our model is also likely to depend on temperature. This makes rigorous analysis of temperature dependence challenging. A simple estimate can be obtained in the frame of Arrhenius law with activation energy equal to the energy height of the nonlinear resonance $E_r = 16\varepsilon \omega_c E_F/\omega$ where $E_F$ is the Fermi energy. This dependence appears as an additional damping factor in ZRS amplitude in a way similar to temperature dependence of Shubnikov-de Haas oscillations leading to

$$R_{xx} \propto \exp(-A\varepsilon \omega_c/(D\omega)) \exp(-16\varepsilon \omega_e E_F/\omega T_e)$$

(4)

Our prediction on activation energy $E_r$ is in a good agreement with experimental data and reproduces the proportionality dependence on magnetic field observed in [1, 2]. For a typical $\varepsilon = 0.01$ we obtain $E_r \sim 20$ K at $j = 1$. The proposed mechanism can find applications for microwave induced stabilization of ballistic transport in magnetically confined quantum wires [20].

In summary we have shown that microwave radiation can stabilize edge trajectories against small angle disorder scattering. For propagating edge channels a microwave field creates a nonlinear resonance well described by the Chirikov standard map. Dissipative processes lead to trapping of particle inside the resonance. Depending on the position of the resonance center in respect to the edge the channeling of particles can be enhanced or weakened providing a physical explanation of ZRS dependence on the ratio between microwave and cyclotron frequencies. In the trapping case transmission along the edges is exponentially close to unity, naturally leading to an exponential drop in $R_{xx}$ with microwave power. Our theory also explains the appearance of large energy scale in temperature dependence of ZRS. A complete theory should also take into account quantum effects since about ten Landau levels are typically captured inside the resonance. A microscopic treatment of dissipation mechanism is also needed for further theory development.
