(Dated: Dec. 29, 2015)

In this article, we obtain a local, BRST-invariant action for QCD at finite temperature, altered from Fadeev-Popov theory due to the presence of Gribov copies. We carefully derive the horizon condition at finite temperature. Only the zero Matsubara mode is affected, and this result is consistent with the suitably modified Maggiore-Schaden shift, which takes into account temporal periodicity. The large-N limit and other calculational schemes for the magnetic mass and gluon condensates and their relation to the Gribov mass are also discussed.

I. INTRODUCTION

Quantum Chromodynamics (QCD) at high temperatures is one corner of the standard model that is still wrought with mystery, and is an active area of research. Questions involving the very early universe, as well as the interior of neutron stars are both limited by our lack of understanding of the hypothesized Quark Gluon Plasma (QGP), presumed to exist at high temperatures. Intuitively, due to asymptotic freedom one would expect that at high temperatures, typical momentum transfers are large so quarks should behave like free particles. From the lattice data \cite{1}, the equation of state does approach a Stefan-Boltzmann limit, supporting this hypothesis. There’s another theory, however, that also shows similar ideal-gas behavior at high temperatures: $\mathcal{N}=4$ super Yang-Mills in the Large $N$ limit. This theory, while integrable, is very strongly coupled and doesn’t behave simply like free particles \cite{2}.

Another sign that this analysis of finite-temperature QCD may be more subtle than our naive intuition is that in the high-temperature limit, the time direction becomes vanishingly small and thus decouples and the action dimensionally reduces\cite{2}

\begin{equation}
S = \frac{1}{\hbar} \int_0^{\beta \hbar} d\tau \int d^d x \mathcal{L}_{\text{QCD}} \rightarrow \beta \int d^d x \mathcal{L}_{\text{QCD}},
\end{equation}

where $D = d + 1$ is the total spacetime dimension with $d$ the number of spatial dimensions. Thus the high-temperature limit of a quantum field theory becomes classical\cite{1} in a sense (no more $\hbar$) in one less dimension. We know however, due originally to Feynman \cite{3}, that 3-D QCD is a confining theory. Thus if we took asymptotic freedom at face value, a 4-D theory of free particles would parametrize a confining 3 dimensional field theory – an odd proposition.

On a much more concrete level, QCD is plagued by infrared divergences in ways that its abelian cousin, Quantum Electrodynamics (QED) is not. The most important object to calculate in statistical mechanics is the partition function. From this object, all thermodynamic quantities of interest can be obtained by merely calculating the gradients of this function along various directions in parameter space. In QED, one can calculate the partition function perturbatively to arbitrarily high powers in the coupling, $\alpha$. In QCD, no such construction has been found. While non-perturbative information is similarly obtained by summing an infinite number of so-called ring diagrams \cite{4}, and a Debye mass is dynamically generated for $A_0$ not unlike QED, one quickly runs into trouble at higher orders due to the non-linearity of gluon-gluon scattering. By adding more and more gluon loops to a perturbative calculation of the free energy, one obtains diagrams of the same order, $g^n$, in the Yang Mills coupling constant \cite{5}. This also similarly occurs at order $g^4$ when calculating higher order contributions to the gluon self energy. This phenomenon was originally pointed out by Linde in 1979 \cite{6}.

Since many issues of finite-temperature QCD seem to be related to its infrared behavior (as with most mysteries about QCD) it seems logical that a clue for how to ameliorate this problem may be related to an inconsistency with our formulation of gauge theory that is very prominent in the infrared, namely the Gribov Ambiguity.

In 1978, Gribov published his famous paper \cite{7} where he showed that the Fadeev Popov (FP) method of gauge fixing was incomplete. He did this by inferring that zero modes of the FP operator imply that each transverse gauge connection has copies

\begin{itemize}
\item [\textsuperscript{\dag}] Intuitively this is due to the fact that at high temperatures, occupation numbers are high which corresponds to the classical limit.
\end{itemize}
belonging to the same gauge orbit. Singer shortly thereafter showed that finding a gauge fixing condition that would lead to a globally defined, continuous gauge condition which behaved well at infinity was generically impossible for non-abelian gauge theories due to the highly non-trivial topology of the space of gauge orbits.

By defining a region that drastically reduced this redundancy, Gribov worked out the dynamical consequences that the elimination of these copies could have. What he found led to clues piercing into the heart of confinement and kicked off a now mature, four-decade old research program. Of interest to us, is that his alterations to the configuration space of gauge connections affects the infrared sector of the theory dramatically: the gluon propagator now vanishes at $k = 0$ due to the presence of an infrared regulator known as the “Gribov mass” and the pole is removed from the real line. The ghost propagator on the other hand obtains an enhanced singularity which, as is shown in an accompanying paper, is related to the divergence of the color-Coulomb potential. This same enhancement was shown by Reinhardt to imply that the QCD vacuum is a dual color superconductor, thus expelling electric flux the way that traditional superconductors expel magnetic flux.

In the following sections, we’ll see how contributions to the finite-temperature partition function for Yang Mills theory restricted to the Gribov region should be constructed. We’ll find that it’s not as simple as just imposing temporal periodicity. We’ll also see that this subtlety reflects ones inability to perform the Maggiore-Schaden shift with a periodic time coordinate. In the last sections we’ll review attempts at calculating contributions to thermodynamic quantities in the presence of the Gribov mass. We’ll discuss recent attempts to understand the magnetic mass and what role the Gribov mass may play in this story. We’ll find that the local GZ action at finite temperature doesn’t affect classical solutions to the gauge field.

Finally in an appendix we see that at high temperature, one can carry out the calculation of the horizon condition perturbatively in the zero-temperature, dimensionally-reduced euclidean theory and this will yield results consistent with first taking the sum over Matsubara frequencies and then taking the high-temperature limit. This shows that the gap equation at high temperature is the same as at zero temperature in one less dimension, consistent with (1).

II. REVIEWING THE GRIBOV HORIZON AT ZERO TEMPERATURE

Since Gribov’s 78 paper, a multitude of results and observations have been achieved from attempting to cleanse the configuration space of gauge copies that survive after covariant gauge fixing. The Gribov region, $Q$, is defined to be the set on which the FP operator, $\mathcal{M}(A)^{ab}(x,y) \equiv (-\partial \cdot D)^{ab}(x)\delta(x-y)$, is positive definite:

$$Q = \{ A^a_\mu : (\theta^a, \mathcal{M}(A)^{ab}\theta^b) > 0, \forall \theta \}$$

where $\theta$ is an arbitrary $L^2$ function, and the inner product is the usual inner product on $L^2$ space. The FP ghost kinetic term is precisely of this form so Gribov began his analysis by doing a semi-classical calculation to investigate where the 1PI ghost propagator crossed from positive to negative, away from the usual pole at $k = 0$. This is the so-called “no-pole” condition. Since then, others have refined this technique to obtain the horizon function from the no-pole condition. This is the functional of $A^a_\mu$:

$$H(A) \equiv \int d^Dx d^Dy D^{ab}_\mu(x) D^{bc}_\mu(y) [(\mathcal{M}(A))^{-1}]^{bc}(x,y),$$

which characterizes the Gribov region $Q$ by the condition $H(A) \leq (N^2 - 1)dV$. The surface in configuration space at which $H(A) - (N^2 - 1)dV$ goes from positive to negative is known as the “Gribov horizon”, $\partial \Omega$. It was shown in that this region is bounded, convex, contains the perturbative region near $A^a_\mu = 0$ and is intersected by every gauge orbit. Then, borrowing an analogy from statistical mechanics when enforcing the constant energy constraint in the canonical ensemble, one can add this non-local constraint to the action. Akin to requiring that the ensemble average yields the desired energy, the non-perturbative constraint to restrict configuration space to the Gribov region is given by

$$\langle H(A) \rangle = (N^2 - 1)dV$$

From here, the non-local term was localized by adding a BRST quartet of new ghost fields, $\phi, \bar{\phi}, \omega, \bar{\omega}$, leading to the Gribov-Zwanziger (GZ) action. It was shown that this action was renormalizable and contained many new symmetries, including

---

3 Shown here in Landau gauge

4 This argument wouldn’t apply when the space of connections is a one dimensional integral as in Coulomb gauge in 1+1 dimensions. In this gauge in 1+1 dimensions the horizon condition factorizes and only contributes a constant to the action and the restriction to the Gribov region becomes vacuous.
a spontaneously broken BRST, and it is conjectured that this allows one to define the space of physical states in Hilbert space for a well-defined MS shift. For the sake of completeness, the form of the final GZ action (here expressed in Landau gauge) is given by
\[
\mathcal{L}_{GZ} = \frac{1}{4} F^\mu_\nu + \tilde{\omega} D^\mu A_\mu - \tilde{\omega} D^\mu \phi_a (D^\mu c)^a + \tilde{\omega} D^\mu \phi_b (D^\mu c)^b \phi_c - \tilde{\omega} D^\mu \phi_d (D^\mu c)^d \phi_e + \gamma 1^{2/2} \left[ (\phi - \bar{\phi})_{\mu \nu} - (D^\mu c \times \phi_{\mu \nu})^a \right] - \gamma D(N^2 - 1);
\]
where \(\gamma\) is the so-called ‘Gribov parameter’. \((A \times B)^a\) is defined to be \(gf^{abc} A^b B^c\). The horizon condition can be reexpressed as
\[
\left( (gA_\mu \times (\phi_{\mu \nu} - \bar{\phi}_{\mu \nu}))^a - (gD_\mu c \times \phi_{\mu \nu})^a \right) = 2\gamma^{1/2}(N^2 - 1)D.
\]
The horizon condition can be obtained via an exact, implicit formula for the eigenvalues of the FP operator. This is done by splitting the FP operator into two contributions:
\[
M^{ac} = M^{ac}_0 + M^{ac}_1 = -\partial^2 \bar{\delta}^{ac} - g f^{abc} A_\mu \partial_\mu .
\]
Notice we’ve used the transversality of the gauge field to commute the derivative through \(A_\mu\). One can then solve the eigenvalue problem at low \(k\) to see how the degenerate space of eigenmodes of the Laplacian splits and eventually crosses through \(\lambda = 0\). This approach will be the one taken here to find the finite-temperature horizon condition.
An altogether different way of implementing this constraint was later found by Maggiore and Schaden (MS) \[15\]. They simply added a BRST quartet of fields,
\[
\begin{align*}
\phi = \phi & \quad \omega = 0 \\
\phi = \bar{\phi} & \quad \bar{\phi} = 0.
\end{align*}
\]
which is shown in \[11\] to not effect physical states. They added to the action an s-exact term, \(s(\bar{D}\bar{\omega}D\phi)\), made up of these fields. Next they hypothesized a peculiar, non-translationally invariant field redefinition, parametrized by a dimensionful quantity, \(\gamma\), the same as the Gribov parameter above and related to the Gribov mass,
\[
\begin{align*}
\phi_{\mu a}(x) & \to \phi_{\mu a}^\prime(x) - \gamma^{1/2} x_\mu \bar{\phi}_a^\prime \\
\bar{\phi}_{\mu a}(x) & \to \bar{\phi}_{\mu a}^\prime(x) + \gamma^{1/2} x_\mu \phi_a^\prime \\
b^a(x) & \to b^a(x) + i\gamma^{1/2} x_\mu f^a(\phi(x)) \\
c^a(x) & \to c^a(x) + i\gamma^{1/2} x_\mu f^a(\bar{\phi}(x)),
\end{align*}
\]
where \(f^a[X] \equiv f^{abc} X^b_\mu(x)\). The value of this parameter was shown to be non-zero at the minimum of the effective action, thus they obtained a lower vacuum around which to define their perturbative fields. Demanding that \(\gamma\) be defined by minimizing the effective action is equivalent to the horizon condition \[5\] and, remarkably, this procedure yields exactly the GZ action.\(^5\)
After integrating out the new ghosts, one arrives back to the non-local action, which is the integral representation of limiting configuration space to the Gribov region \((DA \to DA \Theta(H(A)))\). Not only does this remarkable self-consistency bolster our confidence in the procedure, but it also sheds light on the explicit (but soft) BRST breaking in the GZ action. From the point of view of the MS shift, BRST is spontaneously broken only in the ghost sector \[17\], which allows one to still use cohomology to construct the physical Hilbert space. This is an essential ingredient to quantizing a gauge theory and we would like any implementation of the Gribov horizon at finite temperature to have this feature.

One can see however, that a naïve ‘non-compact time to compact time’ procedure will not be consistent with the MS field redefinition, which depends linearly on time for the temporal components of the ghosts. The fields that were once periodic in \(\tau \to \tau + \beta\) will no longer be periodic post MS shift, but increase linearly with \(\tau\) and become multivalued in a manner akin to the natural logarithm function in the complex plane.

In the next section we’ll see how properly implementing exact degenerate theory techniques with a compact direction leads to a well defined MS shift.

### III. THE HORIZON AT FINITE TEMPERATURE

First, let us recall a bit of the discussion in the Introduction. Remember that at high temperatures, the theory is effectively \(D - 1 = d\) dimensional due to the decoupling of the non-zero Matsubara modes whose excitation energy goes like \(2\pi n T\). The

\(^{5}\) We’d like to point out that this field redefinition has explicit \(x_\mu\) dependence and hence doesn’t vanish at infinity. As in the case of the Higgs VEV, this takes us to a different Hilbert space. For a critique of this procedure see \[19\].
mode of the gauge connection which can feel this compact direction have a finite wavelength and thus for them, $M_0$ dominates over the perturbation $M_1$ by a finite, positive value, and the restriction to the Gribov region has no effect. Since the horizon, $\partial \Omega$, should most strongly impose constraints on the IR degrees of freedom (where the Laplacian is small), we should expect that the Gribov procedure should most strongly affect the IR fields, namely $A_i$, not $A_0$.

We first start in a finite volume, $V = L^d$, and treat $M_1$ as a perturbation. There the spectrum can be well approximated by the spectrum of Laplacian, $\lambda_k = k^2$, where $k$ is the wave number of the unperturbed eigenmodes. The lowest value of this eigenvalue at finite volume is $(2\pi/L)^2$. We then turn on the perturbation adiabatically and simultaneously take the spatial infinite-volume limit. Due to the fact that the color structure of the perturbation is completely antisymmetric and thus tracesless, there are at least some negative eigenvalues of $M_1$. Because of this, as we ramp up the perturbation, the spectrum will lower in some color directions, on top of the fact that the whole spectrum is lowering uniformly as we take the infinite-volume limit. What is crucial here, is that the higher Matsubara frequencies will never be the first modes to cross since they are strictly greater than the zero mode by an amount that remains finite in the infinite-volume limit, being dependent on the size of the compact direction, which is only a function of temperature. Thus when looking at the implicit formula for the eigenvalues, which schematically takes the form of a scattering problem

$$\lambda = \lambda_0 + \langle M_1 \rangle + \sum_{\text{states}} \langle k | M_1 - \frac{1}{\pi} M_1 | k \rangle,$$

we need only consider states with $k_j = (0, k_j)$ because these modes will determine the location of the horizon.

In an accompanying paper [9], we work out the details of this procedure in the general case. To summarize, the first order perturbation vanishes since $M_1$ is traceless. The location of the horizon ($\lambda = 0$) reduces the implicit eigenvalue equation for what happens to an eigenvalue that came out of the degenerate subspace of the Laplacian, labeled by $| \tilde{k} \rangle$, down to the form

$$\lambda_{|\tilde{k}\rangle}(gA) = 0 = k^2 \left(1 - \eta^{-1} \sum_{\tilde{k}' |\tilde{k}\rangle} \tilde{k}' \tilde{k} K^{\eta}_{ij}(\tilde{k}; gA)\right),$$

where $\eta = (N^2 - 1)\sum_{|\tilde{k}|} \tilde{k}$ 1 is the degree of degeneracy of the eigenvalue that we’re perturbing due to the cubic symmetry of the Laplacian. The summation notation means sum over all $\tilde{k}$’s with norm given by $| \tilde{k} |$. The expectation value of the regularized horizon function, $K_{ij}(\tilde{k}, gA)$ given by

$$K_{ij}(\tilde{k}, gA) \equiv V^{-1} \int d^D x d^D y \exp[i\tilde{k} \cdot (\vec{y} - \vec{x})] D_{i}^{\mu}(x) D_{j}^{\nu}(y) (M^{-1})^{\mu \nu}(x, y).$$

is the correlator introduced by Kugo and Ojima, $\langle D_i^a \bar{D}_j^b \rangle$.

The small $k$ limit of this expression, which is of interest to find the first eigenvalue to cross $\partial \Omega$, is discussed in gory detail in [9]. What is important to us is the fact that the indices of the regularized horizon function are not over $\mu$ and $\nu$ but rather $i$ and $j$.

In the accompanying paper this was because the discussion was about Coulomb gauge, but for our finite-temperature discussion, this is because, when the operator $M_1$ acts on the states of interest, it brings out a factor of $k_i$, not $k_\mu$ because the zero Matsubara

\[\text{Figure 1: A graphical map of how to define the Gribov region.}\]
mode will be the first to cross the horizon. Thus even when considering Landau gauge, the horizon condition still takes this form. A change of gauge changes only the form of \( \mathcal{M} \), and for the Landau gauge is still given by \( \mathcal{M} = -D_\mu \partial_\mu \).

This gives the following horizon condition

\[
\left\langle \int d^D x d^D y \, D_i^{ab}(x) D_i^{ac}(\mathcal{M}^{-1})^{bc}(x,y) \right\rangle = V d(N^2 - 1).
\] (7)

**A. The Local Action at Finite Temperature**

Above, we saw how using the horizon condition at finite temperature required one to not only compactify time as usual, but also to alter the horizon condition from \( D_\mu D_\mu \) to \( D_i D_i \). How does this new change manifest itself in the local, GZ form of the action?

When introducing auxiliary ghosts to localize this condition in Landau gauge, we typically give them a Lorentz structure similar to the covariant derivative structure in the horizon condition because in the end we’d like to make Lorentz scalars of these objects (see the term \( D_\mu (\bar{\phi}_\mu - \phi_\mu) \) in \( \mathcal{L}_{GZ} \), where the color structure is contracted treating \( D \) and \( \phi \) in the adjoint representation.)

Our results imply that in the GZ action one should use auxiliary ghosts which transform according to \( SO(d) \) instead of \( SO(D) \) (for the Euclidean theory of course, \( SO(1,d) \) in Minkowski space.) yielding

\[
\mathcal{L}_{GZ} = \frac{1}{4} F_{\mu \nu}^2 + i \partial_\mu b \cdot A_\mu - i \partial_\mu c^a (D_\mu c)^a + \partial_\mu \bar{\phi}_i^a (D_\mu \phi_i) - \partial_\mu \bar{\phi}_i^a \cdot (D_\mu \omega_i + D_\mu c \times \phi_i)^a \\
+ \gamma^{1/2} \left[ D_i^{ab} (\bar{\phi} - \bar{\phi})_i^{ab} - (D_i c \times \bar{\omega}_i)^a \right] - \gamma d(N^2 - 1); \quad (8)
\]

This means even in Landau gauge, the local horizon condition \([5]\) becomes

\[
\left\langle g F^{abc} A_i^a \left( \bar{\phi}_i^{bc} - \bar{\phi}_i^{bc} \right) - (D_i c \times \bar{\omega}_i)^a \right\rangle = 2 \gamma^{1/2} (N^2 - 1) d.
\]

According to the standard lore, at high temperatures \( A_0 \) is parametrically more more massive than \( A_i \) and decouples. The ratio of masses between \( A_0 \) (\( m_{\text{Debye}} \sim gT \)) and \( A_i \) (\( m_{\text{magnetic}} \sim g^2 T \)) vanishes like the coupling as a function of temperature. Recall in Coulomb gauge, the instantaneous part of the \( \langle A_0 A_0 \rangle \) propagator is bounded from below by the Wilson potential that is shown via lattice to be linearly rising. Thus in Coulomb gauge this decoupling appears in the non-instantaneous contribution, responsible for Debye screening. This means we expect the difference between our result and the naive construction of the GZ action in Landau gauge at very high temperature to be a small perturbation. At intermediate temperatures however, this can have a sizable effect on performing perturbative calculations with the GZ action.

The most remarkable feature of this simple result is that it is consistent with the well defined MS shift at finite temperature,
not affecting the periodicity conditions imposed by computing the partition function. Specifically

\[ \phi_{\mu}^{\alpha}(x) \rightarrow \phi_{\mu}^{\alpha}(x) - \gamma^{\prime/2} x_{i} 8_{i}^{\mu} \]
\[ \bar{\phi}_{\mu}^{\alpha}(x) \rightarrow \bar{\phi}_{\mu}^{\alpha}(x) + \gamma^{\prime/2} x_{i} 8_{i}^{\mu} \]
\[ b^{\mu}(x) \rightarrow b^{\mu} + \gamma^{\prime/2} x_{i} f_{i}^{ab} 8_{i}^{\alpha} \]
\[ c^{\mu}(x) \rightarrow c^{\mu} + \gamma^{\prime/2} x_{i} f_{i}^{ab} \bar{8}_{i}^{\alpha}. \]

We take the perspective that the action with spontaneously broken, as opposed to soft BRST breaking, is primary because in that case we believe we know how to define physical states and observables.\[17]\]

### IV. APPLICATIONS FOR FINITE TEMPERATURE

A number of authors have used the GZ action to extend our knowledge about finite-temperature Yang-Mills further into the non-perturbative regime.\[20\][22]. Our perspective in light of the altered GZ action is that it is convenient to use Coulomb gauge. The Coulomb gauge is a unitary gauge which has the same symmetries as the thermal bath, namely spatial isotropy, but not invariance with respect to boosts. Also, as previously mentioned, the horizon condition should be purely an IR effect, and in Coulomb gauge, the full horizon condition only involves the spatial fields which don’t decouple in the high temperature limit. If one is worried about perturbative renormalizability, much progress has been made to show that infinities cancel.\[23\], however a rigorous proof of existence of perturbation theory in Coulomb gauge is still lacking. In the following, we’ll discuss what to expect from using the GZ action at finite temperature regarding the magnetic mass and large N.

#### A. Coupling Constant Expansion, the Magnetic Mass and Condensates

As was previously mentioned, the free energy of a thermal bath of gluons is not perturbatively calculable in a coupling constant expansion the same way it is for QED. With Yang–Mills coupling \( g \), one starts to run into infrared divergences when attempting to calculate \( g^{6} \) contributions. To give a physical picture for the origin of this non-perturbative physics, Gross et al in their ’81 review on finite-temperature QCD showed that if one were to attempt to estimate the contribution to the free energy of topologically unstable Wu-Yang monopoles, one would find an \( O(g^{6}) \) contribution to the free energy. Their back-of-the-envelope calculation was intended to bolster the intuition that non-perturbative effects from the effectively \( (D - 1) \) dimensional gauge theory at high temperature become unavoidable at a high enough order in \( g \).

In the presence of new Bose fields in the GZ action, we should make sure the analysis about monopoles is still applicable. That is, we need to show that the equations of motion for the gauge field are not affected by the auxiliary ghosts. This can be easily demonstrated for the ghosts introduced by the Fadeev-Popov procedure. Since the equations of motion are gauge dependent, let us consider the following gauge-independent observable

\[ G \equiv \left\langle \frac{\delta S}{\delta A_{\mu}^{a}(x)} \frac{\delta S}{\delta A_{\mu}^{a}(x)} \right\rangle. \]

The contribution to the Lagrangian from gauge fixing to the Landau gauge is simply

\[ L_{FP} = s \left( \partial_{\mu} c A_{\mu} \right), \]

where the prime derivatives stand for \( \partial_{\mu}^{\prime} = (a \partial_{\mu}, \partial_{\mu}) \) which allows us to cover all interpolating gauges from Landau (\( a = 1 \)) to Coulomb (\( a = 0 \)) and \( s \) is the usual BRST transformation. After performing the variation, one obtains

\[ \frac{\delta S}{\delta A_{\mu}^{a}} = D_{\mu}^{ab} F_{ab}^{\mu} + \partial_{\mu}^{\prime} b^{a} - g \partial_{\mu}^{\prime} c \partial_{\mu}^{\prime} c. \] (9)

\( G \) can then be written

\[ G = \left\langle (D_{\mu} F_{\mu})^{2} \right\rangle + s \left\{ \partial_{\mu}^{\prime} \partial_{\mu}^{\prime} \bar{c} (\partial_{\mu}^{\prime} \bar{c} \times c) + D_{\mu} F_{\mu} \cdot \partial_{\mu}^{\prime} \bar{c} \right\} \]

\[ = \left\langle (D_{\mu} F_{\mu})^{2} \right\rangle, \]

with the last line following from the fact that BRST is unbroken by the Fadeev-Popov contribution to the action. The following questions remain: can the equivalent observable, \( G \), in GZ theory be written as the Yang-Mills squared equation of motion plus an s-exact term, and secondly, is the expectation value of this s-exact contribution zero?
The pre-MS shifted contribution to the Lagrangian takes the following simple form (suppressing color indices and Lorentz indices on auxiliary ghosts for readability)

\[ \mathcal{L}_{GZ} = s(\partial'_\mu \bar{\phi} \partial^\mu \phi). \]

Thus the contribution to the equations of motion are

\[ \frac{\delta \mathcal{S}_{GZ}}{\delta A_\mu} = -g \partial'_\mu \bar{\phi} \times \phi + g \bar{\phi} \partial'_\mu \bar{\phi} \times \omega - g^2 (\partial'_\mu \bar{\phi} \times \phi) \times c = s(-g \partial'_\mu \bar{\phi} \times \phi) + g(-g \partial'_\mu \bar{\phi} \times \phi) \times c. \]

The second equality is written to reflect the equivalent form of equation (9) above, which can be rewritten

\[ \frac{\delta \mathcal{S}_{FP}}{\delta A_\mu} = s(\partial'_\mu \bar{\phi} \times \phi) + g(\bar{\phi} \partial'_\mu \bar{\phi} \times \omega) \times c. \]

Now the equations of motion take the form

\[ \frac{\delta S}{\delta A_\mu} = D_\mu F_{\lambda \mu} + s X_\mu + g X_\mu \times c, \]

with

\[ X_\mu = \partial'_\mu \bar{\phi} - g \partial'_\mu \bar{\phi} \times \phi. \]

It can then be easily checked that

\[ G = \langle (D_\mu F_{\lambda \mu})^2 \rangle + s \big\{ 2 D_\mu F_{\lambda \mu} X_\mu + X_\mu (s X_\mu + g X_\mu \times c) \big\}, \]

with \( X_\mu \) being an arbitrary color and Lorentz vector. Thus, as expected, soliton solutions to Yang-Mills will indeed be solutions to the classical equations of motion to GZ theory, provided the \( s \)-exact contribution to the equations of motion has a vanishing vacuum expectation value. This condition is trivial for the FP action because the vacuum is BRST invariant. With the GZ action, the vacuum breaks BRST spontaneously and the vanishing of the expectation value of an \( s \)-exact operator is only to be expected for the restricted class of observables mentioned in \([17]\), and when the horizon condition is imposed. Checking this by hand was done for the stress-energy tensor of the theory, and the term relevant in constructing the Kugo-Ojima confinement criterion argument in \([17]\), but for the equations of motion, we will have to simply make use of the unproven conjecture that observables do not break BRST symmetry. Checking the vanishing of this term explicitly will be left for future work and would provide a very non-trivial check of the expectation that BRST holds exactly when needed.

The estimation of the effect of 3-dimensional monopole configurations can be interpreted as a magnetic mass for the spatial gluons. Karabali and Nair give a thorough treatment of Yang Mills theory in 3 spacetime dimensions \([24]\). Similarly to how holomorphic coordinates aid one in calculations of electrodynamics in \(2+1\) dimensions, holomorphic coordinates have also proven to be useful in the Karabali-Nair formalism. As well as treating space as a single complex variable, they also explicitly calculate the functional measure for a change of field space coordinates from the gauge fields to gauge-invariant quantities. In this way they circumvent the Gribov ambiguity because the description no longer has a gauge redundancy. This allows them to estimate certain non-perturbative objects, like the magnetic mass in terms of the dimensionful 3D coupling. In \([25]\) Nair estimates for the magnetic mass, \( m = g^2 N / 2 \pi \) where \( g \) is now the three dimensional coupling constant which is related to the 4-D one by \( g_3^2 T = g_4^2 \) in the high temperature dimensionally reduced picture.

Jackiw et al in \([26]\) began a program of calculating the magnetic mass by simply adding and subtracting a mass term to the Lagrangian. This trivial operation is then interpreted as altering the free propagator to be a massive one (curing IR divergences) and adding a quadratic interaction. By demanding that the value of this mass be self-consistent, one seeks to solve the “Gap Equation”, which is the statement that the value for the added mass should lead to 0 corrections of the gluon self-energy. Others continued this program to 2 loop (\([27]\, [28]\)) and obtained values somewhat off from Nair’s estimate, namely \( g^2 N / 6 \pi \). In the formulation of this technique, nothing guarantees that solving the gap equation at higher loop order leads to a parametrically better approximation to the magnetic mass. A cross check with another technique is needed.

The new and improved propagators of the GZ action come equipped with an infrared cutoff that naively would cure the divergences that plague finite-temperature QCD. Furthermore, it has been shown that the horizon condition yields a Gribov mass on the order of \( g^2 T \), precisely that of the magnetic mass \([29]\). The relation between the Gribov mass and the magnetic mass supports the hypothesis that the non-trivial topology of the space of gauge orbits is a crucial aspect to understanding the phenomenology of non-abelian gauge theories.

This doesn’t solve the problem however; the Gribov mass would still receive contributions from higher order gluon self-energy diagrams, and be just as difficult to calculate as the magnetic mass or \( \Lambda_{QCD} \). One could argue that all we’ve done is moved the
non-perturbative physics from the fully resummed magnetic mass to the value of the Gribov mass. This could be advantageous however because it gives us another way to parameterize our ignorance. The value of the Gribov mass is given by the horizon condition, a non-perturbative formula which might be easier to estimate than the perturbative expansion for the magnetic mass.

For example, the GZ approach yields an alternative perturbation scheme as a cross check to the results obtained by the program mentioned above. Instead of calculating the mass gap in the three dimensional theory, we perturbatively solve for the Gribov mass in the full 4-dimensional theory. This scheme is a dual perturbation, where one calculates the contributions to the free energy to lowest order in $g$ treating the Gribov mass, $m$ as $O(g^0)$. Then you solve the horizon condition to that order and find the $g$ dependence of the Gribov mass. You then plug in that ansatz for $m$ and move to the next order in the coupling constant expansion, and proceed from there. In [29] this procedure was used to find the first-order high-temperature contribution to the non-perturbative scale of the QGP equation of state, and in Appendix A we show that this procedure is consistent with doing the same calculation in the dimensionally reduced theory as a non-trivial cross check. The result to lowest order is $m/T = g^2N/6\sqrt{2\pi}$, not far from the estimate of Cornwall et al [27] for the magnetic mass given above.

The Gribov mass is also relevant for physics regarding condensates. For example, as is nicely reviewed in [30], the dynamical mass of the dressed gluon propagator can be used to calculate the glueball spectrum, which can be related to the gluon condensate, $\langle F_{\mu\nu}^a F_{\mu\nu}^a \rangle$. The gluon mass spectrum has been fit quite well in the context of refined GZ theory, in [31] which uses the GZ action with phenomenological corrections. An old result [32] relates the quantum anomaly, $A$, in the trace of the stress energy tensor of QCD to the beta function and the value of the gluon condensate,

$$A = \frac{\beta(g)}{2g} \langle \langle F_{\mu\nu}^a F_{\mu\nu}^a \rangle \rangle .$$

Similarly, one can calculate the trace anomaly in the context of GZ theory, which will be depend on the Gribov mass. The tree level result from [17] yields

$$A \sim -N^2 \left( \frac{3m^4}{4(2\pi)^2} \right) .$$

Again, this gives a dual perturbation for calculating the gluon condensate, simultaneously expanding the trace anomaly and the horizon condition as above.

**B. Large-N**

Finally, we would like to mention that a potential research direction would be to use the GZ action at finite temperature to provide a different approach to large-$N$ QCD. Thinking about the effects of a gauge-fixing ambiguity resulting from non-trivial topologies has been studied in the past in a much better understood setting. Haber et al [33] studied the $\mathbb{CP}^{N-1}$ model with unconstrained fields and noticed that a gauge redundancy existed due to precisely the pole of $\mathbb{CP}^{N-1}$ which gives this sigma-model its non-trivial topology. Only a subset of fields in this model have this residual gauge freedom, but in the large-$N$ limit, this set of measure-zero gets emphasized, meaning the expectation-value of the fields is precisely the value at which the ambiguity resides. This is similar to how in the infinite-volume limit, the horizon condition puts the measure of configuration space on the horizon which, as shown in [9], is also a geometrically privileged set of configurations. Haber et al found that this special set of fields led to a singularity in the Hamiltonian, not unlike the one found in [9], and that this singularity is responsible for the IR confinement of the theory.

The Gribov mass could be more than another way to parameterize our ignorance about $(D-1)$ dimensional confining theories, it could perhaps lead to a better $1/N$ expansion. From Nair’s reformulation of 3-D QCD, the Gap equation, and the Horizon condition approach, it seems perturbatively stable that the magnetic mass is exactly proportional to $N$. Gracey’s two-loop results for the Horizon condition [34] also suggest that this result persists at higher order.

As we show in the Appendix A the Gribov mass gives another dimensionful parameter in the dimensionally reduced theory. Thus in the case of a $D = 4$ gauge theory at high temperature, we have two dimensionful quantities: the 3-dimensional coupling constant given by $g_3^2 = g_T^2 T$ and the Gribov mass, $m$. The ratio between these two is of order $1/N$. Thus we now have a small parameter in the theory to potentially reorganize the perturbation theory. Recall in the large-$N$ limit $g_T^2$ goes to zero, which corresponds to large $T$ which is exactly where the 3 dimensional description becomes valid. An interesting remark, is that this doesn’t mean that the effect of the Gribov horizon decouples in the large-$N$ limit. The parameter in the MS shift is related to the

---

8 Those authors referred to this as a sort of Gribov ambiguity as well [33].
Gribov mass by

\[ \gamma^{1/2} = \frac{m^2}{\sqrt{N} \bar{g}}. \]  

(10)

In terms of the 't Hooft parameter, \( x = g^2 N \) which remains fixed in the large-N limit, \( m \sim x \) (see Appendix A) and \( \gamma \sim x^3 \).

V. CONCLUSION

In this chapter we’ve revisited the analysis of finding the Gribov region using degenerate perturbation theory; we argue that only the zero Matsubara mode must be considered. This intuitive result dovetails nicely with the assumption that the Gribov procedure is a correction due to the non-trivial topology of the equivalence classes of gauge orbits, and only IR physics should feel this non-triviality. This correction to the horizon condition has implications for what form of the GZ action one should use in various gauges. The correct form of the GZ action happens to coincide with the only well-defined MS shift procedure at finite temperature which is a nice self-consistency check for the theory, since the MS shift allows us to define physical states despite the apparent BRST breaking of the usual GZ action. Since the Gribov mass provides an infrared cutoff, it could play an important role in calculating the value of the magnetic mass. The extent of the role of the Gribov ambiguity in illuminating non-perturbative physics is still unknown at this point, but certainly it gives us an alternative approach to understanding these effects.

Acknowledgements

We recall with pleasure stimulating conversations about this work with Geoff Ryan, Luke Underwood, Martin Schaden and Eliezer Rabinovici.

Appendix A: Commuting of the High Temperature Limit

Above we described a procedure for calculating the Gribov mass perturbatively in the high-temperature limit. This was done by truncating the horizon condition at a certain order of the coupling, \( g \), while treating the Gribov mass, \( m \), as \( O(g^0) \). After summing over Matsubara frequencies, we can then look at the horizon condition in the limit \( T \to \infty \) to get a closed for expression for \( m(g,T) \). However, there is a completely different way of taking the high temperature limit. At high \( T \) (low \( \beta \)), the compact direction becomes vanishingly thin, and what results is an effectively \( d \) dimensional, zero temperature euclidean field theory with \( g_4^2 = T g_3^2 \). In this appendix, we shall calculate the horizon condition to low order in arbitrary euclidean dimensions, and show that the 3D result, with \( g_3^2 = g_3^2 T \) yields the exact expression derived for the finite temperature 4-dimensional Gribov mass.

Thus the perturbative procedure described above for imposing the horizon condition commutes with the order in which you take the high temperature limit and one can avoid matsubara sums altogether at high temperature by using the dimensionally reduced theory.

For arbitrary euclidean space dimension, \( d \), the functional integral up to quadratic terms is given by

\[ Z = e^W = \int dA db dc d\bar{c} d\phi d\bar{\phi} d\omega d\bar{\omega} \ e^{-S}; \]

with

\[ S = \int d^d x \left( \frac{1}{4} F_{\mu \nu}^a F^{a \mu \nu} + i \partial_{\mu} b A_\mu - i \partial_{\mu} \bar{c} \partial_{\mu} c + \partial_{\mu} \bar{\phi} \partial_{\mu} \phi + \partial_{\mu} \bar{\omega} \partial_{\mu} \omega + \frac{g}{\gamma} \gamma^{1/2} f^{abc} A_\mu^a (\phi_\mu - \bar{\phi}_\mu)^{bc} - \gamma d(N^2 - 1) \right) \]

where \( \gamma \) is given by \( \gamma \) and \( F_0 \) means \( F \) restricted to the linear terms in \( A \). Note, here \( d \) is arbitrary and \( \mu, \nu \) range from 1, \ldots, \( d \).

We will use it for \( d = 3 \) in the end, so that in that case \( \mu, \nu \) would be \( i, j \) to be consistent with what’s presented above. Integration over the fermi ghosts \( c, \bar{c} \) and the Nakanishi-Lautrup field \( b \) implements the Landau gauge condition, leaving only the transverse part of \( A_\mu \). One can also perform the field redefinition \( \bar{\phi} \),

\[ \bar{\phi}_{\mu} \to \bar{\phi}_{\mu} + g \gamma^{1/2} (-\partial^2)^{-1} f^{abc} A_{\mu}^c \]

This will diagonalize \( \phi \)'s kinetic term at the cost of adding to the action the term

\[ g^2 \gamma f^{abc} A_{\mu}^a (-\partial^2)^{-1} f^{abc} A_{\mu}^d. \]
The inverse determinant which results in integrating out the shifted bose ghosts cancels the determinant from integrating out the auxiliary fermi ghosts and we’re left with
\[
S = \int d^4x \left( \frac{1}{2} \partial_\mu A_\nu^r \cdot \partial_\mu A_\nu^r + m^2 A_\mu^r \cdot (-\partial^2)^{-1} A_\mu^r - \gamma d(N^2 - 1) \right).
\]

Focusing on the quadratic part of the action, \( S_0 \), we have
\[
e^{W_0} = \int dA^{\mu r} e^{-S_0} = \left( \det^{-1/2} \left[ -\partial^2 + \frac{m^4}{d} \right] \right)^{(N^2-1)(d-1)} = \exp \left( -\frac{1}{2} (N^2-1)(d-1) V \int \frac{d^d k}{(2\pi)^d} \ln \left( k^2 + \frac{m^4}{k^2} \right) \right).
\]

Including the constant part of the action, the free energy, \( W \), is then given by
\[
W = W_0 = \frac{(N^2-1)d m^4 V}{2 N^2 g^2} - \frac{(N^2-1)(d-1) V}{2} \int \frac{d^d k}{(2\pi)^d} \ln \left( k^2 + \frac{m^4}{k^2} \right).
\]

The horizon condition to this order can then be written
\[
0 = \frac{\partial W}{\partial m^4} = \frac{d}{g^4 N} - (d-1) \int \frac{d^d k}{(2\pi)^d} \frac{1}{(k^2)^2 + m^4}.
\]

One can then evaluate the integral, yielding
\[
I_d = \int \frac{d^d k}{(2\pi)^d} \frac{1}{(k^2)^2 + m^4} = \frac{1}{m^{4-d}} \frac{\pi}{2} \frac{\Gamma(2-d/2)}{\Gamma \left( \frac{1}{2} \left[ \frac{d}{2} + 1 \right] \right) \Gamma \left( \frac{1}{2} \left[ 3 - \frac{d}{2} \right] \right)}.
\]

\( d = 3 \) gives us
\[
I_3 = \frac{1}{4\sqrt{2\pi}}.
\]

Thus the horizon condition in 3 dimensions holds for a Gribov parameter given by
\[
m = \frac{g_3^2 N}{3 \cdot 2^{3/2} \pi}.
\]

If we’re to believe the high-temperature limit where the 4 dimensional theory with coupling constant, \( 1/g_4^2 \), is replaced by a three dimensional theory with coupling, \( 1/(g_3^2 T) \equiv 1/(g_4^2) \), then we better get the same dependence of \( m \) on \( g \) that we found in the high-temperature limit previously calculated in the strictly 4D theory. Indeed, by taking the three dimensional result of equation (A1) and making the proper replacement, we have
\[
m = g_4^2 T \frac{N}{3 \cdot 2^{3/2} \pi}.
\]

This agrees with equation (94) in [29], thus confirming that taking the high-temperature limit in these two different ways does indeed yield the same result in this calculational scheme. This effectively allows us to analyze the high-temperature limit of finite-\( T \) GZ theory by doing a standard calculation in zero temperature euclidean field theory, thereby avoiding the infinite sum over Matsubara frequencies in the intermediate steps before taking the limit.

**Appendix B: On Level Crossing**

One important assumption is made when moving from a sum over the set of eigenvalues of the Fadeev-Popov operator that emerge from the degenerate subspace of the Laplacian operator when the perturbation, \( gA_\mu(x) \partial_\mu \), is turned on, to the average of these eigenvalues. That is, that we can’t have a situation where the average is zero, but some of the individual eigenvalues emerging from that degenerate sub-space could be very non-zero. This would violate our definition of the Gribov region, as well as call into question the stability of the ghost kinetic term, which would no longer be positive definite.
The crux of the argument is that if one takes a generic eigenvalue of the Laplacian, the splicing of that degenerate subspace into its non-degenerate spectrum will be sandwiched between the non-degenerate spaces of the higher and lower eigenvalues of the Laplacian. In the infinite-volume limit, the spectrum of the Laplacian becomes continuous, therefore the span of that non-degenerate space becomes infinitely thin, and the average represents any one of the eigenvalues arbitrarily well. This ‘sandwiching’ caused by the absence of level crossing is a big assumption, but is well supported by work on early atomic physics dating back to Wigner and von Neumann [35]. They show that for a 1 or 2 parameter family of adiabatic perturbations of a Hermitian operator, levels will generically repel each other unless a symmetry principle allows otherwise. The symmetries of the unperturbed operator in our case, the Laplacian, are the generators of $SO(d)$. The FP operator does not share these symmetries, or for generic $A_i$, any symmetries at all, so its eigenstates will not fall into different irreducible representations which allow for generic level crossing. There are two important caveats to this. One, is the case of accidental crossing. Without an explicit calculation of the full spectrum this could never be disproved, however the set of gauge fields with these crossings should have a very small measure and contribute little to the path integral. The second caveat is more severe, namely that these proofs about level crossing are typically for finite dimensional matrices, but in order to justify the concentration of measure on the boundary of the Gribov region, we must take the infinite volume limit. At this moment we can offer nothing to ease the skeptics’ mind on that issue.
