Abstract. The association between Helicobacter pylori (\textit{H. pylori}) infection and metabolic syndrome (MetS) determined in different cohorts from different countries is currently inconclusive. In the majority of previous studies, \textit{H. pylori} infection was diagnosed based on the presence of \textit{H. pylori} IgG antibody in the serum. However, to the best of our knowledge, only few studies have investigated the association between \textit{H. pylori} infection and MetS using the urea breath test (UBT) as a diagnostic tool. The present study was performed with the aim of providing a detailed analysis of the association between \textit{H. pylori} infection, as diagnosed by the UBT method, and MetS in a large community from Zhejiang province in eastern China. The results indicated that \textit{H. pylori} infection increases the risk of MetS in the aged female population.

Introduction

Metabolic syndrome (MetS) comprises a group of metabolic abnormalities, including central obesity, impaired glucose tolerance, insulin resistance (IR), lipid metabolism disorders and hypertension, which markedly increase the risk of diabetes mellitus and cardio-cerebrovascular disease (1-3). Approximately one-quarter of the population worldwide have been reported to suffer from MetS (2). Chronic inflammation was previously suggested to be implicated in MetS (4).

Helicobacter pylori (\textit{H. pylori}) infection is one of the most common infections globally, affecting >50% of the world’s population, particularly in developing countries. Its prevalence varies across different cohorts with differences in age and developmental status (5,6). \textit{H. pylori} infection may cause chronic gastritis, peptic ulcers and gastric cancer (7-9). More recently, \textit{H. pylori} gastritis was considered as an infectious disease (10). \textit{H. pylori} infection has been indicated to increase systemic inflammation by producing inflammatory factors, including C-reactive protein (CRP), tumor necrosis factor-\(\alpha\), interferon-\(\gamma\) and interleukin-1, -6 and -8, and these factors were confirmed to be involved in the pathogenesis of IR (11,12). In addition to gastrointestinal infections, \textit{H. pylori} has also been reported to be associated with various extra-intestinal diseases, including MetS (13-20).

At present, the association between \textit{H. pylori} infection and MetS determined in different cohorts of different countries remains inconclusive (17,20-32). In the majority of those studies, \textit{H. pylori} infection was diagnosed based on the presence of \textit{H. pylori} IgG antibody in the serum (29-31); however, serum IgG may persist after \textit{H. pylori} is eradicated and may therefore not reflect the current infection status (33). The \(^{13}\text{C}\)-urea breath test (UBT) is a non-invasive method for detecting current \textit{H. pylori} infection. The sensitivity and specificity of the UBT are ~0.96 [95% confidence interval (CI): 0.95-0.97] and 0.93 (95% CI: 0.91-0.94), respectively (34). While it may be assumed that only current infection is able to cause systemic inflammatory reactions, few studies have investigated the association between \textit{H. pylori} infection and MetS using UBT as the diagnostic method, to the best of our knowledge.

Therefore, given the diversity of the incidence of \textit{H. pylori} infection across different countries and the controversial results of the studies investigating the association between \textit{H. pylori} infection and MetS, particularly in East Asia, it is crucial to further investigate this association in a large population. The aim of the present study was to provide a detailed analysis of the association between \textit{H. pylori} infection, as diagnosed by UBT, and MetS in a large community from Zhejiang province in eastern China.
Materials and methods

Study participants. Participants who voluntarily underwent a general health screening between January 2014 and December 2015 were recruited at the International Health Care Center of the Second Affiliated Hospital of Zhejiang University School of Medicine (Hangzhou, China). Participants with any of the following characteristics were excluded from the study: i) History of gastric surgery; ii) history of anti-\textit{H. pylori} therapy; iii) use of antibiotics, proton pump inhibitors, H2 blockers or bismuth within the previous 4 weeks; iv) severe mental or neurological disorders; v) history of cancer(s). All subjects underwent a detailed physical examination, including UBT detection of \textit{H. pylori} infection.

Diagnosis of \textit{H. pylori} infection. After fasting for at least 2 h, all of the participants underwent a $^{13}$C-UBT (Richen-Force, Beijing, China) for the detection of \textit{H. pylori} infection. After collecting the baseline breath sample, the participants ingested a $^{13}$C-urea reagent dissolved in water. The second breath sample was collected and analyzed after 30 min. A delta over baseline value ≥4.0 indicated a positive result for \textit{H. pylori} infection.

Definitions of the study variables. For each participant, age, sex, weight, height, body mass index (BMI) and waist circumference were recorded. Blood pressure was measured after at least 10 min of rest. Waist circumference was measured with a measuring tape while standing, midway between the lowest rib and the iliac crest. The BMI was calculated as follows: Weight (kg)/height (m)$^2$.

Information on the history of smoking and alcohol consumption, as well as the medical history, including hypertension, hyperlipidemia and/or diabetes, was also collected using a questionnaire. The questionnaire also included the history of the present illness, previous diagnoses of \textit{H. pylori} infection, history of anti-\textit{H. pylori} therapy and confirmation of eradication after treatment. If the questionnaire was incomplete, the patient was contacted to ensure for integrity of the data.

Laboratory examinations were performed after a 10-h fast, including white blood cell (WBC) count, hemoglobin (Hb), platelet count, high-sensitivity (HS)-CRP, total cholesterol, low-density lipoprotein cholesterol, high-density lipoprotein cholesterol (HDL-C), triglyceride (TG), total bilirubin, alanine aminotransferase (ALT), aspartate aminotransferase (AST), fasting plasma glucose, glycylated Hb (HbA1c), 2-h postprandial plasma glucose, glycosylated hemoglobin (HbA1c), fasting insulin, C-peptide, low-density lipoprotein cholesterol, high-density lipoprotein cholesterol, plasma glucose (mmol/l), or previous diagnosis of type 2 diabetes mellitus, or the patient receiving corresponding treatment.

IR is generally considered to be the most important pathophysiological basis for MetS. The homeostasis model assessment (HOMA) score may be used to estimate IR, which is defined as follows: (Fasting plasma insulin (mU/l) x fasting plasma glucose (mmol/l))/22.5. A high HOMA-IR score denotes low insulin sensitivity and IR (36). Based on a previous study (17), three cut-off values of the HOMA-IR index (2, 2.5 and 3) were adopted to evaluate IR.

Statistical analysis. The statistical analysis was performed using IBM-SPSS 24.0.0.0 software (IBM Corp.) and Python. Wilcoxon's rank-sum test was used to evaluate differences between groups for quantitative data, and the Chi-squared test was used for qualitative data. All P-values were based on a two-sided test of statistical significance. P<0.05 was considered to indicate a statistically significant difference. The optimal cut-off point of age was calculated using the maximization of Youden's index (sensitivity+specificity−1) in the receiver operating curve analysis. The association between \textit{H. pylori} status and MetS characteristics was evaluated by a multivariate logistic regression (LR) analysis model following adjustment for age, sex, alcohol consumption, smoking, WBC count, HS-CRP, ALT, AST, HbA1C, HCY, CYSC, Cr and UA levels. The patients were further stratified into subgroups based on age and sex.

Results

Clinical and demographic characteristics. In the present study, 5,884 participants were included after screening of a total of 10,602 subjects (Fig. 1). The study subjects had a mean age of 46.8±10.13 years and 2,053 (34.9%) were female. A total of 1,265 (21.5%) had MetS, with a different percentage among males and females (24.8 vs. 15.3%, respectively; P<0.001). In addition, the prevalence of MetS was identified to increase with age, particularly in females.

The overall prevalence of \textit{H. pylori} infection in this cohort was 46%, and it was higher in male compared with female patients (47.1 vs. 43.9%, respectively; P=0.023), however, it did not exhibit any differences across different age groups.

A statistically significant difference in the presence of \textit{H. pylori} was observed between subjects with and those without MetS (50.4 vs. 44.8%, respectively; P<0.001; Table I).

Overall, age and sex subgroup analyses for the risk of MetS associated with \textit{H. pylori} infection. A multivariate LR model was constructed for predicting MetS by considering the \textit{H. pylori} infection status and other potential covariates, including sex, age and HOMA-IR. It was observed that \textit{H. pylori} infection was a significant risk factor contributing to the prediction of MetS with a broad-line risk of 1.2 (95% CI: 1.02-1.36, P=0.028; Table II). Subsequently, a receiver operating characteristic curve analysis on age was performed to segment participants, which indicated the age of 50 years as an optimal threshold (i.e., maximizing Youden's index; Table III). It was also used to differentiate the MetS distribution between subjects with or without \textit{H. pylori} infection. Furthermore, A multivariate LR model analyses revealed that
H. pylori infection was a significant risk factor for MetS in male participants aged <50 years and in female participants aged ≥50 years (Table IV).

Multivariate LR analysis of H. pylori infection and other factors with MetS. A multivariate LR analysis was performed to determine the risk of MetS associated with the H. pylori infection status and other metabolic-associated parameters.
which were not direct variables in defining MetS, including WBC count, HS-CRP, ALT, AST, HbA1c, HCY, CYSC, Cr and UA. It was observed that *H. pylori* infection, age, sex, HS-CRP, HbA1c, UA and Cr were also positively associated with MetS (Table V). When stratifying participants into different gender groups and different age groups, similar patterns among contributors for predicting MetS were revealed. It was noted that, when the subjects were stratified by sex and further by age, *H. pylori* infection was significantly associated with MetS in female patients aged ≥50 years (odds ratio (OR)=1.29, 95% CI: 1.09-1.91; Table VI).

### Discussion

The present study investigated the prevalence of *H. pylori* infection in subjects with MetS, and further explored the association of *H. pylori* infection and other factors with MetS. A significant difference was identified in the presence of *H. pylori* infection between subjects with and those without MetS (50.4 vs. 44.8%, respectively; P<0.001). In a multivariate LR analysis, *H. pylori* infection was determined to be significantly associated with MetS in female patients aged ≥50 years.
Several studies have identified _H. pylori_ infection as a risk factor for MetS (17,20-25). Chen et al (17), reported that the prevalence of MetS was higher among _H. pylori_-positive individuals of either gender in a Chinese adult cohort. Upala et al (21) demonstrated that _H. pylori_ infection was positively associated with IR using a meta-analysis. Yang and Xuan (25) indicated that elderly patients (aged 73.19±11.03 years) with _H. pylori_ infection had a higher BMI and fasting glucose levels and a higher incidence of MetS. Furthermore, certain studies suggested that _H. pylori_ infection has a causative association with MetS through pathophysiological analysis (26-28). By contrast, other studies failed to prove this association (29-32). For instance, Naja et al (31) reported no suggested association of _H. pylori_ infection with IR or MetS in Lebanese adults. Similarly, Tamura et al (32), identified no association between _H. pylori_ infection and diabetes in a Japanese population.

In addition to national and regional factors, these inconsistent results may be due to the different screening methods for _H. pylori_ infection among different studies. _H. pylori_ infection is diagnosed on the basis of clinical and laboratory findings, as well as microbiological and histopathological examinations following endoscopy. Shin et al (37), observed that MetS was more closely associated with histological positivity for _H. pylori_ (adjusted OR=1.26, 95% CI: 1.08-1.48) rather than serological positivity (adjusted OR=1.12, 95% CI: 0.95-1.32). This conclusion was attributed to the fact that serological positivity for _H. pylori_ does not necessarily indicate current infection. Only few studies have been performed to assess the effects of _H. pylori_ infection on MetS in Chinese populations, and most of those are based on the detection of IgG antibody in the serum. Although Chen et al (17) used ^13^C-UBT to demonstrate that _H. pylori_ infection is positively associated with MetS, the systemic association among MetS, _H. pylori_ infection and other variables has remained to be elucidated.

In the present study, a different prevalence of _H. pylori_ infection was observed between male and female subjects (47.1 vs. 43.9%, respectively; P=0.023), whereas Chen et al (17) reported a similar prevalence in either gender (20%) in an adult population from Taiwan. In addition, there was no difference in the prevalence of _H. pylori_ infection among different age groups; however, they reported an increase in prevalence with advancing age in males and females (17). Those results indicate a different prevalence (also between the two sexes) of MetS and _H. pylori_ infection across the Chinese population, suggesting that different measures have to be taken accordingly. In addition, the present study also observed a difference in the prevalence of MetS between sexes (24.8 vs. 15.3% in male and female subjects, respectively), consistently with the results of a more recent study (38).

This association was further investigated by stratifying the subjects into males and females, and into different age groups. An increased significance was observed in aged females, which was consistent with a previous study reporting that _H. pylori_ infection was a predictor of MetS in elderly patients (aged 73.19±11.03 years) (25). Although in the present study, _H. pylori_ infection was significantly associated with MetS, it was observed that _H. pylori_ infection per se was only a weak predictor of MetS (accuracy, 65%) regardless of sex and age (all these models achieved an accuracy of ~65%). Furthermore, _H. pylori_ infection was not the major contributor in the LR model compared with other metabolism-associated parameters, but it may be an important contributor to MetS when combined with other factors. Due to the higher incidence of hyperlipidemia, hyperglycemia or hypertension among individuals aged >50 years, _H. pylori_ infection has a greater impact in this population. In addition, it has been demonstrated that post-menopausal females have significantly reduced estrogen levels, reduced resistance to inflammatory reactions and increased levels of inflammatory factors (39,40), which may explain for the more pronounced inflammatory response of aged females to _H. pylori_ infection compared with males.

The health check-up population at our center mainly comprised residents from Zhejiang province, so the economic level is expected not to differ significantly. In fact, the questionnaire included queries associated with socioeconomic conditions and eating habits. However, a previous statistical analysis indicated that their impact was not significant, so they were not included in the present study.

Of note, the present study had certain limitations. First, the subjects were recruited from a single center. Second, the present study was an observational study, and conclusions may only be drawn regarding the association between _H. pylori_ infection and other factors with MetS.

In conclusion, _H. pylori_ infection increases the risk of MetS in aged females. However, these observations are inconsistent across different cohorts, which warrants further investigation by prospective or biochemical studies. If confirmed, eradication of _H. pylori_ infection may be of therapeutic value for MetS.
