The evolution of effective force chains percolating through a compressed granular system is investigated. We performed experiments by compressing an ensemble of spherical particles in a cylindrical container monitoring the macroscopic constitutive behavior and the acoustic signals emitted by microscopic rearrangements of particles. As a novel approach, we applied the continuous damage model of fiber bundles to describe the evolution of the array of force chains during the loading process. The model provides a nonlinear constitutive behavior in good quantitative agreement with the experimental results. For a system of hard particles the model predicts a universal power law divergence of stress when approaching a critical deformation. The amplitude distribution of acoustic signals was found experimentally to follow a power law with exponent $\delta = 1.15 \pm 0.05$ which is in a good agreement with the analytic solution of the model.

FIG. 1. Experimental set up and sketch of the array of force chains used in the model.
In the present letter the generation and evolution of percolating force chains is studied experimentally and theoretically in granular packings subjected to an uniaxial external load. We measured experimentally the macroscopic constitutive behavior and the acoustic signals emitted by microscopic restructuring events compressing an ensemble of spherical glass bead confined in a cylinder. Based on the analogy of force lines percolating through the system and fibers of a fiber composite we propose a novel theoretical approach, namely, an inversion of the Continuous Damage Model (CDM) of fiber bundles [8,9] to describe the stress transmission through granular assemblies. The model naturally captures the emergence and gradual hardening of force chains and provides analytic solutions for the constitutive behavior and acoustic activity as well. We also propose an efficient Monte Carlo simulation technique.

![Graph](image1)

**FIG. 2.** Constitutive behavior measured experimentally. A power law with exponent 2.6 was fitted to the data. The comparison with the analytic solution of the model is also presented.

In our experiments a cylindrical container made of PMMA was filled with glass beads of 5 mm diameter and water. The cylinder has a thickness of 5 mm and a diameter of 140 mm. A punch test was carried out applying monotonically increasing displacements at the top level of the glass beads. Eight acoustic sensors were placed at the container wall to record the signals emitted during the compression of the beads, as can be seen in Fig. 2. The actual force and the displacement, measured at the traverse of the loading machine, and the acoustic signals were recorded simultaneously. An eight channel transient recorder was used as an analogue-digital converter to enable the storing of the acoustic emission waveforms and a signal-based data. Experiments were performed under strain controlled conditions at a fixed strain rate, i.e. moving the traverse at a constant speed of 1 mm/minute.

The nonlinear elastic response of the system can be observed in Fig. 2 where the measured force $F$ is presented as a function of strain $\varepsilon$ imposed. A power law of an exponent 2.6 was obtained as a best fit to the measured data in reasonable agreement with former experiments of Ref. [8].

The emergence and gradual hardening of force chains is responsible on the microscopic level for the strong non-linearity observed macroscopically. To obtain information about microscopic processes, the acoustic waves emitted due to sudden relative displacements of particles were monitored. Typically several hundred signals were recorded during the experiment. The inset of Fig. 2 shows the automatically extracted peak amplitudes of the burst signals versus time. The energy is defined as the integral of the acoustic emission signal amplitude following the onset time. The energy values of the acoustic emissions are summed up in intervals of 30 seconds to elucidate the time dependent evaluation of acoustic emission activity. More details of acoustic emission data analysis and especially signal-based techniques can be found in [10,11]. The statistics of restructuring events is characterized by the distribution $D(s)$ of the height of peaks $s$, which is presented in Fig. 3 on a double logarithmic plot. It can be seen that $D(s)$ shows a power law behavior over two orders of magnitude, the exponent of the fitted straight line is $\delta = 1.15 \pm 0.05$.

![Graph](image2)

**FIG. 3.** The statistics of acoustic signals. A power law of an exponent $\delta = 1.15 \pm 0.05$ was fitted to the size distribution of the signals of the inset.
by a redistribution of load on the remaining intact fibers according to the range of interaction in the system. The so-called Continuous Damage Model introduced recently [9], is particularly suited to model granular materials since it captures gradual stiffness changes of elements of the model. In our model of compressed packings, force lines formed by particles are represented by an array of lines organized in a square lattice as illustrated in the inset of Fig. 1. A randomly distributed rearrangement thresholds \( d \) is assigned to each line of the array from a distribution of the same functional form, \( \varepsilon \). However, the characteristic strength \( \varepsilon \) of the distribution is increased in a multiplicative way so that after \( k \) rearrangements, \( \varepsilon \) has the property \( \varepsilon \rightarrow \infty \) for \( k \rightarrow \infty \). Hence, the number of force lines \( N \) has finite values only for \( \varepsilon < \varepsilon^* \), where \( \varepsilon \) is a material parameter. The maximum possible number of percolating force chains \( N_o \) that can emerge in the system was estimated as the ratio of the total area of the container \( A_o \) to the cross section of a single particle \( A_p \), i.e. \( N_o = A_o \). The value of the other parameters are \( E_o = 4600 \frac{N}{mm^2}, d_o = 3N, \beta = 0.01 \) and \( \alpha = q = 1.01 \). The value of \( a \) falls close to one indicating that a single restructuring gives rise only to a slight increase of stiffness of a force chain. Model calculations revealed that the zero derivative at the starting part of the constitutive curve is due to the gradual creation of load bearing force chains. The small value of \( \beta \) implies that the generation of new force chains stops at a relatively small strain value, and hence, the later rapid increase of \( F \) as function of \( \varepsilon \) is mainly caused by the hardening of the existing force lines. Further information can be gained about the constitutive behavior for larger strains by simplifying Eq. (3) assuming a fixed number \( N_o \) of force chains from the beginning of the process. Under this assumption Eq. (3) can be reformulated as

\[
\sigma(\varepsilon) = E_o \varepsilon [1 - P_0(\varepsilon)] + a^{k_{max}} E_o \varepsilon P_0(\varepsilon)^{k_{max}}.
\]

It can be seen from Eq. (3) that if the maximum number \( k_{max} \) of possible restructuring events goes to infinity the stress \( \sigma \) has finite values only for \( aP_0(\varepsilon) < 1 \). In this case the summation can be performed in the first term, while the second term tends to zero, and the constitutive equation takes the form

\[
\sigma(\varepsilon) = E_o \varepsilon [1 - P_0(\varepsilon)] \frac{1}{1 - aP_0(\varepsilon)}.
\]

It follows that the stress \( \sigma \) diverges when \( \varepsilon \) approaches a critical value \( \varepsilon_c \), where \( \varepsilon_c \) satisfies the equation \( P_0(\varepsilon_c) = 1/a \). Expanding \( P_0(\varepsilon) \) into a Taylor series at \( \varepsilon_c \) as

\[
P_0(\varepsilon) = P_0(\varepsilon_c) + p_1(\varepsilon_c)(\varepsilon - \varepsilon_c) + \ldots,
\]

and substituting it into Eq. (3) the behavior of \( \sigma \) in the vicinity of \( \varepsilon_c \) reads as

\[
\sigma(\varepsilon) = E_o \varepsilon [1 - P_0(\varepsilon)] \frac{1}{1 - aP(\varepsilon_c)(\varepsilon - \varepsilon_c)}
\]

Experiment and discrete element simulations [10] have revealed that the number of effective force chains increases during the compression process until it reaches a saturation value. To capture this effect in our model, for the number of elements we prescribe the form \( N(\varepsilon) = N_0 G(\varepsilon) \), where \( N_0 \) denotes the saturation number of chains, and the profile \( G(\varepsilon) \) has the property \( G(\varepsilon) \rightarrow 1 \) with increasing \( \varepsilon \). Hence, the number of force lines \( dN \) emerging due to an infinitesimal deformation increment from \( \varepsilon \) to \( \varepsilon + d\varepsilon \) is \( dN = N_0 g(\varepsilon) d\varepsilon \), where \( g(\varepsilon) = dG(\varepsilon)/d\varepsilon \). Following the derivation of the constitutive behavior of the continuous damage model of fiber bundles [11], the macroscopic constitutive equation of the compressed granular system can be cast into the form

\[
\sigma(\varepsilon) = E_o \sum_{i=0}^{k_{max}-1} \int_0^\varepsilon a^i (\varepsilon - \varepsilon^*)^i g(\varepsilon^*) P_0(\varepsilon - \varepsilon^*) \times [1 - P_0(\varepsilon - \varepsilon^*)] d\varepsilon^* + \int_0^\varepsilon a^{k_{max}} (\varepsilon - \varepsilon^*)^0 g(\varepsilon^*) P_0(\varepsilon - \varepsilon^*) d\varepsilon^*.
\]
\[ \sigma(\varepsilon) \approx \frac{1}{a p_0(\varepsilon_c)(\varepsilon_c - \varepsilon)} \sim (\varepsilon_c - \varepsilon)^{-1}. \] (4)

It means that the stress \( \sigma \) shows a power law divergence when \( \varepsilon \) approaches the critical value \( \varepsilon_c \). The value of the exponent is universal; it does not depend on the form of disorder distribution \( P_0 \), while the value of \( \varepsilon_c \) depends on it. It is interesting to note that in Ref. [6] the same power law divergence was found in large scale molecular dynamic simulations of a hard sphere system.

When the number of force lines is fixed it is possible to obtain analytic results also for the statistics of restructuring events. Restructuring occurs during the compression process when the local load on a force line exceeds its threshold value. Since loading is performed under strain controlled conditions, there is no load redistribution among existing force lines, i.e. restructuring of a force line does not affect other elements of the system. If the new threshold value, assigned to the force line after rearrangement, is smaller than the local load, the force line undergoes successive restructurings until it gets stabilized. The number of steps to reach the stable state defines the size \( s \) of the restructuring event, which is the analog of the acoustic signals measured experimentally. The number of restructuring events \( N_{k,s} \) of size \( s \) starting in force chains which have already suffered \( k \) restructurings can be deduced as

\[ \frac{N_{k,s}(\varepsilon)}{N_o} = p_0(\varepsilon) P_0^{s+k-1}(\varepsilon) [1 - P_0(\varepsilon)], \] (5)

for \( s + k \leq k_{\text{max}} - 1 \), and

\[ \frac{N_{k,s}(\varepsilon)}{N_o} = p_0(\varepsilon) P_0^{k_{\text{max}}-1}(\varepsilon), \] (6)

for \( s + k = k_{\text{max}} \) (see also Ref. [4]). The number of events \( D(s) \) of size \( s \) can be determined by integrating over the entire loading history and summing over all possible \( k \) values

\[ D(s) = \sum_{k=0}^{k_{\text{max}}-s} \int_0^{\varepsilon_c} \frac{N_{k,s}(\varepsilon)}{N_o} d\varepsilon + \int_0^{\varepsilon_c} \frac{N_{k_{\text{max}}-s,s}(\varepsilon)}{N_o} d\varepsilon. \] (7)

Finally, substituting Eqs. (5,6) into Eq. (7) and performing the calculations yields

\[ D(s) = s^{-1}, \quad \text{where} \quad 1 \leq s \leq k_{\text{max}}, \] (8)

i.e. the distribution of microscopic restructuring events exhibits an universal power law behavior with an exponent 1, which is completely independent on the disorder distribution. Numerical simulations revealed that the universal power law behavior also holds when the gradual creation of force chains is taken into account, i.e. when the system is described by the full Eq. (2). The statistics of restructuring events obtained by Monte Carlo simulations is presented in Fig. 4 where simulations were performed under the assumption \( N(\varepsilon) = N_o(1 - e^{-\varepsilon/\varepsilon_c}) \). The inset shows local events of different sizes that occurred during the loading process, and their distribution is presented in the main figure. The power law behavior of the analytic prediction of eq. (8) is verified. It is important to emphasize that the theoretical results on event statistics (Fig. 4) are in a very good quantitative agreement with the experimental findings (Fig. 3).

![Fig. 4. Inset: local events of size \( s \) from a Monte Carlo simulation of strain controlled loading. The statistics of events \( D(s) \) is presented in a double logarithmic plot.](image)

Note, that the functional form and the value of the exponent of \( D(s) \) in the analytic calculations is mainly the consequence of the locality of restructurings due to the absence of load redistribution. The excellent agreement observed indicates that this is likely the microscopic mechanism responsible for the power law statistics of acoustic signals observed experimentally.
