ABSTRACT
In temporal interaction networks, vertices correspond to entities, which exchange data quantities (e.g., money, bytes, messages) over time. Tracking the origin of data that have reached a given vertex at any time can help data analysts to understand the reasons behind the accumulated quantity at the vertex or behind the interactions between entities. In this paper, we study data provenance in a temporal interaction network. We investigate alternative propagation models that may apply to different application scenarios. For each such model, we propose annotation mechanisms that track the origin of propagated data in the network and the routes of data quantities. Besides analyzing the space and time complexity of these mechanisms, we propose techniques that reduce their cost in practice, by either (i) limiting provenance tracking to a subset of vertices or groups of vertices, or (ii) tracking provenance only for quantities that were generated in the near past or limiting the provenance data in each vertex by a budget constraint. Our experimental evaluation on five real datasets shows that quantity propagation models based on generation time or receipt order scale well on large graphs; on the other hand, a model that propagates data proportionally has high space and time requirements and can benefit from the aforementioned cost reduction techniques.

1 INTRODUCTION
Many real world applications can be represented as temporal interaction networks (TINs) [21], where vertices correspond to entities or hubs that exchange data over time. Examples of such graphs are financial exchange networks, road networks, social networks, communication networks, etc. Each interaction \( r \) in a TIN is characterized by a source vertex \( r.s \), a destination vertex \( r.d \), a timestamp \( r.t \) and a quantity \( r.q \) (e.g., money, passengers, messages, kbytes, etc.) transferred at time \( r.t \).

Figure 1: Example of quantity transfer (FIFO policy)

Objective and Methodology In this paper, we study a provenance problem in TINs. Our goal is to track the origin (source) of the quantities that are accumulated at the vertices over time. To do so, we first need to specify how data are transferred from one vertex to another and when new quantities are generated. In general, we assume that each vertex \( v \) has a buffer \( B_v \) (e.g., bitcoin wallet) [12], wherein it accumulates all incoming quantities to \( v \). Naturally, the buffer \( B_v \) changes over time. Specifically, each interaction \( r \) from a vertex \( r.o \) to a vertex \( r.u \) transfers \( r.q \) units from \( B_{r.o} \) to \( B_{r.u} \) at time \( r.t \). If \( B_{r.o} \) has less than \( q \) units by time \( r.t \), then the difference must be generated at \( r.o \) before being transferred to \( r.u \). In a financial exchange network, generation of new quantities could mean that new assets are brought into the network from external sources (e.g., a user buys bitcoins by paying USD). In a road network, new quantities are cars entering the network from a given location.

We propose solutions that proactively create and propagate lightweight provenance information in the TIN for the generated quantities, as they are transferred through the network. This way, we can obtain the origins of the quantities at vertices at any time. We define and study alternative information propagation models that may apply to different application scenarios. Specifically, consider an interaction \( r \) from a vertex \( r.o \) to a vertex \( r.u \), which transfers \( r.q \) units and assume that \( r.q \) is smaller than the current number of units in buffer \( B_{r.o} \). In this case, \( r.q \) units should be selected from the buffer to be transferred, based on a policy. The selection policy could prioritize quantities based on the time they were first generated at their origins, or on the order they were added to \( B_{r.o} \) or could select quantities proportionally based on their origins. For instance, Figure 1 shows the buffers \( B_v \) and \( B_u \) of two vertices \( v \) and \( u \) before and after an interaction \((v, u, t, 5)\). The quantities in the buffers are organized as a FIFO queue based on their origins (e.g., \( B_v \) contains 4 and 3 units originating from vertex \( w \) and vertex \( z \), respectively). Based on the FIFO policy, all 4 units from \( w \) are selected to be transferred plus 1 unit from \( z \). For each of the selection policies that we consider, we propose provenance update mechanisms and study efficient and space-economic algorithms for annotation propagation.

Previous Work To our knowledge, there is no previous work that studies data provenance in TINs. Within our framework, we define and use data transfer models for TINs, which are based on data relay, i.e., data units that move in the network are not cloned or deleted. On the other hand, most previous works define and study information diffusion models [29, 41], where data items (e.g., news, rumors, etc.) are spread in the network and the main objective is to identify the vertices of maximal influence in the network [25], targeting applications such as viral marketing. Hence, previous efforts on provenance tracing for social networks [3, 45] are based on different information propagation models compared to our work.

Data provenance is a core concept in database query evaluation [6] and workflow graphs [8, 40]. The main motivation is tracing the raw data which contribute to a query output. Data provenance finds use in most types of networks (e.g., threat identification in communication networks [19]). Data provenance can be categorized into: where, how and why provenance [9]. Where-provenance identifies
the raw data which contribute to some output, why-provenance identifies the sources (e.g., tuples) that influenced the output [30–32], and how-provenance explains how the input sources contribute to the output. Our work focuses on solving both the where- and why-provenance problem in TINs, i.e., find the vertices that contribute to each vertex over time. We also extend our solution to support how-provenance, i.e., capture the paths that have been followed by quantities. Our solutions can shed light to the reasons behind the accumulation of a quantity at a given vertex. Key differences to previous work on data provenance are: (i) in our problem, any vertex of the graph can be the origin of a quantity and any vertex can also be the destination of a propagated quantity; and (ii) we support the maintenance of provenance information in real-time, as new interactions take place in a streaming fashion.

Applications Solving our provenance problem in TINs finds application in various domains. In financial networks, tracking the origin of financial units that move between accounts can help in analyzing their relationships. For example, we can identify the accounts that (indirectly) contributed the most in financing a suspicious account. We can also characterize accounts based on whether they receive funds from numerous or few sources, or identify groups of users that finance other groups of users. Another example of a TIN is a communication network, where messages are transferred between vertices and there is a need to trace the origins of malicious messages that reach a vertex. Tracing the origin of such messages can be hard due to IP spoofing [35] and there is a need for specialized techniques [44]. Similarly, in transportation networks (e.g., flight networks or road networks) studying the provenance of problems (e.g., traffic, delays, etc.) may help in finding and alleviating the reasons behind them. As a provenance data analysis example, consider one of the TINs used in our experiments, which captures the transfers of passengers by taxi between NYC districts on 2019.01.01. Figure 2 shows the number of passengers that are accumulated in East Village from other districts. After each transfer, we can analyze the provenance distribution of passengers (shown as pie charts). This can be used to analyze the demographics of visitors over time (e.g., for location-aware marketing).

Figure 2: Buffered quantities at vertex #79 (East Village) after each interaction in Taxis Network

Contributions and outline Our main contribution is the formulation of a provenance tracking problem in temporal interaction networks with important applications. We define different selection policies for the propagation of quantities and the corresponding annotation generation and propagation algorithms. We analyze the space and time complexity of the provenance mechanism that we propose for each selection policy and find that the proportional propagation policy is infeasible for large graphs because its space complexity is quadratic to the number of vertices $|V|$ and each interaction bears a $O(|V|)$ computational cost.

We propose restricted, but practical versions of provenance tracking under the proportional propagation policy. Our selective provenance tracking approach maintains provenance data only from a designated subset of $k$ vertices, which are of interest to the analyst, reducing the space complexity to $O(k \cdot |V|)$ and the time complexity to $O(k)$ per interaction. The grouped provenance tracking approach tracks provenance from groups of vertices instead of individual vertices (e.g., categories of financial entities or accounts). Again, the space and time complexity is reduced to $O(k \cdot |V|)$ and $O(k)$ per interaction, respectively, if $k$ is the number of groups. We also propose two techniques that limit the scope of provenance tracking from all (individual) vertices. The first approach limits provenance tracking up to a certain time in the past from the current interaction (i.e., a time-window approach). The second approach allocates a provenance budget to each vertex. Both techniques save resources, while providing some guarantees with respect to either time or importance of the tracked provenance information.

We extend our propagation algorithms for provenance annotations to capture not only the origins of the generated data, but the routes (i.e., the paths) that they travelled along in the graph until they reached their destinations. We experimentally evaluate the runtime and memory requirements of our methods on five real TINs with different characteristics. Our results show the scalability and limitations of the different selection policies and the corresponding propagation algorithms for provenance data.

The rest of the paper is organized as follows. Section 2 reviews related work on data provenance and TINs. In Section 3, we formally define the provenance problem in TINs. Section 4 presents the different information propagation policies and the corresponding provenance tracking algorithms. In Section 5, we discuss scalable techniques for provenance tracking under the proportional propagation policy. In Section 6, we show how to track the paths of the propagated quantities in the TINs from their origin. Section 7 presents our experimental evaluation. Finally, Section 8 concludes the paper with a discussion about future work.

2 RELATED WORK

There has been a lot of research in data provenance over the years [3, 10, 11, 32, 36, 37, 39, 43]. However, we are the first to study the problem of tracking the origin of quantities that flow in temporal interaction networks. In this section, we summarize representative works in temporal interaction networks and provenance tracking.

2.1 Temporal Interaction Networks

Temporal interaction networks (TINs) capture the exchange of quantities between entities over time and they have been studied extensively in the literature [2, 33, 34]. For instance, Kosyfaki et al. [27] studied the problem of finding recurrent flow path patterns in
2.2 Theory and Applications in Provenance

Buneman et al. [6] were the first who defined and studied the problem of data provenance in database systems. The goal of why-provenance (a.k.a. lineage) is to explain the existence of a tuple \( t \) in a query result by finding the tuples present in the input that contributed to the production of \( t \). Where-provenance finds the exact attribute values from the input which were copied or transformed to produce \( t \). An annotation mechanism for where-provenance was proposed in [7] and implemented in DBNNotes [5]. As query operators (select, project, join, etc.) are executed, annotations are propagated to eventually reach the query output tuples. Annotation propagation depends on the way the query is written/evaluated.

Geerts et al. [15] introduced another annotation-based model for the manipulation and querying of both data and provenance, which allows annotations on sets of values and for effectively querying how they are associated. The focus is on scientific database curation, where data from possibly multiple sources are integrated and annotations are used to witness the association between the base data that produced a curated tuple.

Although our solutions share some similarities to provenance approaches for database systems, there are important differences in the data and the propagation models. First, the TIN graphs that we examine are very large (as opposed to small query graphs) and we track provenance for any vertex in them (i.e., we do not distinguish between input and output vertices). Second, the data transfer model between vertices in TINs is very different compared to data transfer in query graphs. Third, interactions can happen in any order in our TINs, as opposed to query graphs, where edges have a specific order (query graphs are typically DAGs).

Data Provenance has also been studied in social networks [3]. An important application is to detect where a rumor has started before spreading through the internet. Gundecha et al. [18] represent social networks as directed graphs and try to recover paths to find out how information spread through the network by isolating important nodes (less than 1%). The importance of the nodes is based on their centrality. Taxidou et al. [45] studied provenance within an information diffusion model, based on the W3C Provenance Data Model\(^1\). A related problem in social networks is information propagation and diffusion. Domingos and Richardson [13] were the first who studied techniques for viral marketing to influence social network users. Kempe et al. [25] solved the problem of selecting the most influential nodes by proposing a linear model, where the network is represented as a directed graph and vertices are categorized as active and inactive based on their neighbors. These approaches are not applicable to TINs, because, in social networks, information is copied and diffused, whereas in TINs data are moved (i.e., not copied) from one vertex to another. This key difference makes the provenance problem in TINs unique compared to related problems in previous work.

Savage et al. [44] propose a stochastic packet marking mechanism that can be used for probabilistic tracing back packet-flooding attacks in the Internet. The problem setup is quite different than ours, since we target a more generic provenance problem in TINs where information is propagated based on various different models that may not permit backtracing. Moreover, we aim at exact provenance tracking wherever possible.

2.3 Provenance Systems

Over the years, a number of systems for provenance tracking have been developed, mainly to serve the need of efficiently storing and managing the annotation data. Chapman et al. [8] propose a factorization technique, which identifies and unifies common query evaluation subtrees for reducing the provenance storage requirements. Heinis and Alonso [20] represent workflow provenance mechanisms as DAGs and compress DAGs with common nodes, in order to save space.

Several systems [1, 17] have been developed to support the answering of data provenance questions, where the objective is to find how a data element has appeared in the query result. Karvounarakis et al. [23] developed ProQL, a query language which can be used to detect errors and side effects during the updates of a database. ProQL takes advantage of the graph representation and path expressions to simplify operations involving traversal and projection on the provenance graph. Titian [22] adds provenance support to Spark, aiming at identifying errors during query evaluation.

Glavic et al. [16] present a system for provenance tracking in data stream management systems (DSMS). They propose an operator instrumentation model, which annotates data tuples that are generated or propagated by the streaming operators with their provenance. They also propose an alternative approach (called replay lazy), which uses the original operators and, whenever provenance information is needed, the approach replays query processing on the relevant inputs through a instrumented copy of the network (hence, data processing and provenance computation are decoupled). We also propose space-economic models for tracking provenance. However, our input graphs (TINs) are larger and different than DSMS graphs and our propagation models consider the transfer of quantities between vertices as a result of a stream of interactions.

Provenance has also been studied in blockchain systems especially after the huge success of Bitcoin. In [42], a secure and efficient system called LineageChain is implemented on top of Hyperledger\(^2\), for capturing the provenance during contract execution and safely storing it in a Merkle tree.

3 DEFINITIONS

In this section, we formally define the temporal interaction network (TIN) on which our problem applies. Then, we present the data propagation model, which determines the origins of the quantities

---

\(^1\)https://www.w3.org/TR/prov-dm/

\(^2\)https://www.hyperledger.org
which are transferred in the network. Finally, we define the provenance problem that we study in this paper. Table 1 summarizes the notation used frequently in the paper.

**Definition 1 (Temporal Interaction Network).** A temporal interaction network (TIN) is a directed graph \( G(V, E, R) \). Each edge \((v, u) \in E \) captures the history of interactions from vertex \( v \) to vertex \( u \). \( R \) denotes the set of interactions on all edges of \( E \). Each interaction \( r \in R \) is characterized by a quadruple \((r.s, r.d, r.t, r.q)\), where \( r.s \in V \) (\( r.d \in V \)) is the source (destination) vertex of the interaction, \( r.t \in \mathbb{R}^+ \) is the time when the interaction took place and \( r.q \in \mathbb{R}^+ \) is the transferred quantity from vertex \( r.s \) to \( r.d \), due to interaction \( r \).

![Figure 3: A set of interactions and the corresponding TIN](image)

Figure 3 shows a set of interactions and the corresponding graph. For example, sequence \((1, 3), (5, 7)\) on edge \((v_1, v_2)\) means that \(v_1\) transferred to \(v_2\) a quantity of 3 units at time 1 and then 7 units at time 5. The corresponding interactions in \( R \) are \((v_1, v_2, 1, 3)\) and \((v_1, v_2, 5, 7)\).

**Table 1: Table of notations**

| Notation | Description |
|---------|-------------|
| \(G(V,E,R)\) | TIN (vertices, edges, interactions) |
| \(r.s\) | source vertex of interaction \( r \in R \) |
| \(r.d\) | destination vertex of interaction \( r \in R \) |
| \(r.t\) | time when interaction \( r \in R \) took place |
| \(r.q\) | transferred quantity during interaction \( r \in R \) |
| \(B_v, | B_r|\) | buffer of vertex \( v \), total quantity in \( B_r \) |
| \(O(t,B_v)\) | origin (provenance) data for the quantity at \( B_v \) by time \( t \) |
| \(r.o, r.q\) | quantity \( r.q \) originating from \( r.o \) in \( O(t,B_v) \) |
| \(p_v\) | provenance vector of a vertex \( v \in V \) |

We consider all interactions \( R \) in the TIN in order of time and assume that throughout the timeline, each vertex \( v \in V \) has a buffer \( B_v \), which stores the total quantity that has flown into \( v \) but has not been transferred yet to another vertex via an outgoing interaction from \( v \). We use \( |B_v| \) to denote the quantity buffered at \( B_v \).

As an effect of an interaction \((r.s, r.d, r.t, r.q)\), vertex \( r.s \) transfers a quantity of \( r.q \) to vertex \( r.d \). Quantity \( r.q \) (or part of it) could be data that have been accumulated at vertex \( r.s \) by time \( r.t \), or \( r.q \) could (partially) be generated at \( r.s \). More specifically, we distinguish between two cases:

- \(|B_{r,s}| \leq r.q\). In this case, all units from \( B_{r,s} \) are transferred to \( B_{r,d} \) due to the interaction. In addition, \( r.q - |B_{r,s}| \) units are generated by the source vertex \( r.s \), and transferred to \( B_{r,d} \). Hence, \(|B_{r,s}| \) becomes 0 and \(|B_{r,d}| \) is increased by \( r.q \).
- \(|B_{r,s}| > r.q\). In this case, \( r.q \) units are selected from \( B_{r,s} \) to be transferred to \( B_{r,d} \). Hence, \(|B_{r,s}| \) is decreased by \( r.q \) and \(|B_{r,d}| \) is increased by \( r.q \). The selection policy may determine the routes of the quantities in the network and may affect the result of provenance tracking.

**Algorithm 1 Propagation algorithm in a TIN**

**Require:** \( TIN G(V,E,R) \)

1. for each \( v \in V \) do
   2. \( |B_v|=0 \) ➔ initialize buffers
   3. end for
4. for each interaction \( r \in R \) in order of time do
   5. \( q = \min (r.q, |B_{r,s}|) \) ➔ relayed quantity from \( B_{r,s} \)
   6. \( |B_{r,s}| = |B_{r,s}| - q \) ➔ decrease by \( q \)
   7. \( |B_{r,d}| = |B_{r,d}| + r.q \) ➔ increase by \( r.q, r.q-q \) newborn units
   8. end for

Algorithm 1 is a pseudocode of the data propagation procedure. Interactions in \( R \) are processed in order of time. For each interaction \( r \in R \), we first determine the relayed quantity \( q \) from the buffer of the source vertex \( r.s \) (Line 5). This quantity cannot exceed the currently buffered quantity \(|B_{r,s}|\) at \( r.s \). Line 6 decreases \(|B_{r,s}|\) accordingly. The target node’s buffer \( B_{r,d} \) is increased by \( r.q \) (Line 7). If \( r.q > q \), a new quantity \( r.q - q \) is born by the source vertex \( r.s \) to be transferred to \( B_{r,d} \) as part of \( r.q \).

Table 2 shows the changes in the buffers of the three vertices in the example TIN (Figure 3), during the application of Algorithm 1. The values in the parentheses are the newborn quantities at \( r.s \), which are transferred to \( r.d \). In the beginning, all buffers are empty, hence, as a result of the first interaction, 3 quantity units are born at vertex \( v_1 \) and transferred to \( v_2 \), but no previously born quantity is relayed from \( B_{v_0} \) to \( B_{v_2} \). At the second interaction, 3 units move from \( B_{v_2} \) to \( B_{v_2} \) and 2 newborn units at \( v_2 \) are also transferred to \( B_{v_0} \). At the third interaction, 3 units are selected to be transferred from \( B_{v_0} \) to \( B_{v_0} \), and no new units are generated because the \( B_{v_0} \) had more units than \( r.q = 3 \) before the interaction.

**Table 2: Changes at buffers at each Interaction**

| \(r.s\) | \(r.d\) | \(r.t\) | \(r.q\) | \(|B_{v_0}|\) | \(|B_{v_1}|\) | \(|B_{v_2}|\) |
|-------|-------|-------|-------|--------|--------|--------|
| \(v_1\) | \(v_2\) | 1 | 3 | 0 | 0 | 3 (3) |
| \(v_0\) | \(v_1\) | 3 | 5 | 5 (2) | 0 | 0 |
| \(v_1\) | \(v_1\) | 4 | 3 | 2 | 3 | 0 |
| \(v_0\) | \(v_2\) | 5 | 7 | 2 | 0 | 7 (4) |
| \(v_1\) | \(v_1\) | 7 | 2 | 2 | 2 | 5 |
| \(v_0\) | \(v_0\) | 8 | 1 | 3 | 2 | 4 |

Definition 2 formally defines the provenance problem that we study in this paper.

**Definition 2 (Provenance Problem).** Given a TIN \( G(V,E,R) \), at any time moment \( t \) and at any vertex \( v \in V \) determine the origin(s) \( O(t,B_v) \) of the total quantity accumulated at buffer \( B_v \) by time \( t \). \( O(t,B_v) \) is a set of \( (r.o, r.q) \) tuples \( r \), such that each quantity \( r.q \) was generated by vertex \( r.o \) and \( \sum_{r \in O(t,B_v)} r.q = |B_v| \).

At any time \( t \), during Algorithm 1, the objective is to be able to identify the origin vertices which have generated the quantities that have been accumulated at buffer \( B_v \), for any vertex \( v \). Hence,
the problem is to divide the buffer $B_v$ into a set of $(r.o, r.q)$ (origin-quantity) pairs, such that each quantity $r.q$ is generated by the corresponding vertex $r.o$. A data analyst can then know how the total quantity buffered at $v$ has been composed.

4 SELECTION POLICIES AND PROVENANCE

For each interaction $r \in R$, the selection policy in the case where $|B_{r.s}| > r.q$ determines the provenance of the quantities that are accumulated at any vertex $v$ (and transferred from $v$) throughout the timeline. Selection does make a difference because the quantities in a buffer $B_{r.s}$ may originate from different vertices. We present possible selection policies that (i) are based on the time quantities are generated, (ii) are based on the order they are received by the vertex $r.s$ or (iii) choose quantities proportionally based on their origins. For each policy, we present annotation mechanisms that can be used to trace the provenance of the quantities accumulated at the vertices of the TIN. We also discuss applications where these selection policies may apply.

4.1 Selection based on generation time

The first selection policy is based on the time when the candidate quantities to be transferred are generated. Priority in the selection can be given to the oldest quantities or the most recently generated ones depending on the application. We will first discuss the least recently born selection policy. To implement this approach, any generated quantity should be marked with the vertex $v$ that generates it and the timestamp $t$ when it is generated. Hence, during the course of the algorithm, each buffer $B_v$ is modeled and managed as a set of $(o, t, q)$ triples, where $o$ is the origin of the vertex (i.e., the vertex which bore) quantity $q$ and $t$ is the time of birth of $q$. The total quantity $|B_v|$ accumulated at buffer $B_v$ is the sum of all $q$ values in the triples that constitute $B_v$. As a result of an interaction $r$, if $|B_{r.s}| > r.q$, the triples in $B_{r.s}$ with the smallest timestamps whose quantities sum up to $r.q$ are selected and transferred to $B_{r.s}$. The last triple may be partially transferred in order for the transferred quantity to be exactly $r.q$. The triples in each buffer $B_v$ are organized in a min-heap in order to facilitate the selection.

Algorithm 2 describes the whole process. For the current interaction $r \in R$ in order of time, we maintain in variable $resq$ the residue quantity, which has yet to be transferred from $r.s$ to $r.d$. Initially, $resq = r.q$. While $q > 0$ and $B_{r.s}$ is not empty, we locate the least recently born triple $r$ in $B_{r.s}$ (with the help of the min-heap). If $r.q > q$, this means that we should transfer part of the quantity in the triple to $B_{r.d}$, hence, we split $r$, by keeping it in $B_{r.s}$ and reducing $r.q$ by $q$ and initializing a new triple $r'$ with the same origin and birthtime as $r$ and quantity $q$. The new triple is added to $B_{r.s}$. If $r.q \leq q$, we transfer the entire triple $r$ from $B_{r.s}$ to $B_{r.d}$. If $B_{r.s}$ becomes empty and $resq > 0$, then this means that it was $|B_{r.s}| < r.q$ in the beginning, so we should generate a newborn triple $r'$ with the residue quantity $resq$ having as origin vertex $r.s$ and marked to be generated at time $t.r.t.$

Table 3 shows the changes in the buffers of the vertices (shown as sets here, but organized as min-heaps with their middle element $t$ as key) after each interaction of our running example. Note that the quantities in the buffers are broken based on their origins and times of birth.

| $r.s$ | $r.d$ | $r.t$ | $r.q$ | $B_{r.s}$ | $B_{r.d}$ | $B_{r.q}$ |
|-------|-------|-------|-------|-----------|-----------|-----------|
| $c_1$ | $c_2$ | 1     | 5     | $\emptyset$ | $\emptyset$ | $\emptyset$ |
| $d_2$ | $d_3$ | 2     | 3     | $\emptyset$ | $\emptyset$ | $\emptyset$ |
| $d_4$ | $d_5$ | 3     | 7     | $\emptyset$ | $\emptyset$ | $\emptyset$ |
| $e_1$ | $e_2$ | 4     | 2     | $\emptyset$ | $\emptyset$ | $\emptyset$ |
| $e_3$ | $e_4$ | 5     | 1     | $\emptyset$ | $\emptyset$ | $\emptyset$ |

By running Algorithm 2, we can have at any time $t$ the set of vertices that contribute to a vertex $v$ by time $t$ and the corresponding quantities (i.e., the solution to Problem 2). In other words, the heap contents for each vertex $v$ at time $t$ corresponds to $O(t, B_v)$. Finally, to implement the most recently born selection policy, we should change Line 7 of Algorithm 2 to "$	au = \text{most recent triple in } B_{r.s}$ and organize each buffer as a max-heap (instead of a min-heap).

Application The least recently born policy is applicable when the generated quantities lose their value over time (or even expire), which means that the vertices prefer to keep the most recently generated data. On the other hand, the most recently born policy is relevant to applications, where quantities have antiquity value, i.e., they become more valuable as time passes by.

Complexity Analysis In the worst case, each interaction $r$ increases the total number of triples by one (i.e., by splitting the last transferred triple or by generating a new triple), hence, the space complexity of the entire process is $O(|R|)$. In terms of time, each interaction accesses in the worst case the entire set of triples at vertex $r.s$. This set is $O(|R|)$ in the worst case, but we expect it to be $O(|R|/|V|)$; for each triple in the set, we update two priority queues in the worst case (i.e., by triple transfers) at an expected cost of $O(|R|/|V|)$. Hence, the overall expected cost (assuming an even distribution of triples) is $O(|R| \cdot |R|/|V| \cdot |R|/|V|) = O(|R|^2/|V| \cdot |R|/|V|)$. 

Algorithm 2 Least-recently born selection model

Require: TIN $G(V,E,R)$
1. for each $v \in V$ do
2. $B_v = \emptyset$; $|B_v| = 0$ → Initialize buffers
3. end for
4. for each interaction $r \in R$ in order of time do
5. $resq = r.q$ → residue quantity to be transferred
6. while $resq > 0$ and $|B_{r.s}| > 0$ do
7. $\tau = \text{least recent triple in } B_{r.s}$ → top element in heap $B_{r.s}$
8. if $r.q > resq$ then
9. $\tau'.n = \tau.o; \tau'.t = \tau.t; \tau'.q = resq$; → new triple
10. add $\tau'$ to $B_{r.d}$;
11. $\tau = r.q = r.q -$resq;
12. $resq = 0$; → transfers completed
13. else

22. end for
4.2 Selection based on order of receipt

Another policy would be to select the transferred quantities in order of their receipt. Specifically, the quantities at each buffer $B_r$ are modeled and managed as a set of $(o,q)$ pairs, where $o$ is the vertex which generated $q$. These pairs are organized based on the order by which they have been inserted into $B_r$. If, for the current transaction $r$, $|B_{r,s}| > r.q$, the last (or the first) quantities in $B_{r,s}$ which sum up to $r.q$ are selected and added to $B_{r,d}$ in their selection order. To implement this policy, each buffer is implemented as a FIFO (or LIFO) queue, hence, it is not necessary to keep track of the transfer-time timestamps. The algorithm is identical to Algorithm 2, except that Line 7 becomes “least recently added triple in $B_{r,s}$” in the FIFO policy and “most recently added triple in $B_{r,s}$” in the LIFO policy. Table 4 shows the changes in the buffers after each interaction when the LIFO policy is applied.

### Table 4: Changes at buffers (LIFO policy)

| $r.s$ | $r.d$ | $r.t$ | $r.q$ | $B_{r_0}$ | $B_{r_1}$ | $B_{r_2}$ |
|-------|-------|-------|-------|-----------|-----------|-----------|
| $v_1$ | $v_2$ | 1     | 3     | $\emptyset$ | $\emptyset$ | $(1,1,2)$ |
| $v_2$ | $v_0$ | 3     | 5     | $(1,3,2)$  | $(1,3,2)$  | $\emptyset$ |
| $v_0$ | $v_1$ | 4     | 3     | $(1,2)$    | $(1,3,2)$  | $\emptyset$ |
| $v_1$ | $v_2$ | 5     | 7     | $\emptyset$ | $(1,1,2)$  | $(1,1,2,1)$ |
| $v_2$ | $v_1$ | 7     | 2     | $(1,2)$    | $(1,2)$    | $(1,1,2,1)$ |
| $v_1$ | $v_2$ | 8     | 1     | $(1,2,1,1)$| $(1,2)$    | $(1,1,2,1,1)$|
pairs, for each vertex \( u \) contributing a quantity \( q > 0 \) in the buffer \( B_u \). For example, after the temporally first interaction in our running example, instead of storing \( p_{o_d} \) as \( [0, 0, 3] \), we store it as \( [(v_1, 3)] \), implying that \( v_2 \) received its 3 units from \( v_1 \). The vector update operations of Algorithm 3 can be replaced by merging the ordered lists of the corresponding sparse vector representations. This way, the space requirements are reduced from \( O(|V|^2) \) to \( O(|V| \cdot \ell) \), where \( \ell \) is the average length of the list representations of the vectors. The time complexity is reduced to \( O(|R| \cdot \ell) \), accordingly. Still, as we show experimentally, in Section 7, \( \ell \) can grow too large and we may not be able to accommodate the lists in memory, after a long sequence of interactions.

5 SCALABLE PROPORTIONAL PROVENANCE

Proportional provenance tracking (Section 4.3) has high space and time complexity compared to the models based on generation time (Section 4.1) or receipt order (Section 4.2). We investigate a number of techniques that reduce the space requirements and constitute proportional provenance feasible even on very large graphs.

5.1 Selective provenance tracking

In many applications, we may not have to track provenance from all vertices in the graph, but from a selected subset thereof. For example, in a financial network, we could limit our focus to a specific set of entities, suspected to be involved in illegal activities. Or, we may select the \( k \) vertices that generate the largest total quantities. Hence, we can limit the size of the provenance tracking vectors \( p_v \) to include only a given subset of vertices having limited size \( k \).

Specifically, for each vertex \( v \in V \), we maintain a vector \( p_v \) of size \( k + 1 \), where the first \( k \) positions correspond to the vertices of interest and the last position represents the rest of the vertices. Algorithm 3 can now directly be applied, after the following change: if any of the source vertex \( r.s \) or the destination \( r.d \) is not in the set of the \( k \) vertices of interest, we update the \( (k + 1)\)th position, which accumulates the sum of quantities from all vertices except the selected ones. This version of proportional selection algorithm has reduced space and time complexity compared to Algorithm 3. Specifically, its space requirements are \( O(k \cdot |V|) \) and its time complexity is \( O(k \cdot |R|) \).

5.2 Grouped provenance tracking

In practice, tracking provenance from individual vertices could provide too many details which might be hard to interpret. It might be more practical, to track provenance from groups of vertices. Hence, assuming that the vertices of the TIN have been divided into groups, we can replace the long \( p_v \) vectors by shorter vectors of length \( m \), where \( m \) is the number of groups. This means that, in the end, for each vertex \( v \) we will have in \( p_v \) the total quantity in the buffer \( B_v \) of \( v \) which originates from each group. The grouping of vertices can be done in different ways depending on the application. For example, the values of one or more attributes that characterize the vertices in the application (e.g., gender, country) can be used for grouping. Network clustering algorithms (e.g., METIS [24]) or geographical clustering can be used to divide the vertices to groups.

Algorithm 3 can easily be adapted to operate on groups. The vertices involved at each interaction (i.e., \( r.s \) and \( r.d \)) are mapped to group-ids and the corresponding positions are updated in the vector-wise operations. As in the case of selective provenance tracking (Section 5.1), the space and time complexity is reduced to \( O(m \cdot |V|) \) and \( O(m \cdot |R|) \), respectively.

5.3 Limiting the scope of provenance

If selective and grouped provenance is not an option, tracking proportional provenance in large graphs with millions of vertices could be infeasible. We investigate two techniques that limit the scope of provenance by either avoiding the tracking of quantities generated far in the past or setting a budget for provenance at each vertex. Our techniques are especially suitable for streaming data, where speed and feasibility are preferred over preciseness.

5.3.1 Windowing approach. Our first approach takes as input a parameter \( W \), representing a window, which determines how far in the past we are interested in tracking provenance. Specifically, for each vertex \( v \) we can guarantee finding the provenance of quantities that reach \( v \), which where born up to \( W \) interactions before. To achieve this, for each \( v \), we initialize two sparse (i.e., list) provenance vector representations \( p_v^{\text{odd}} \) and \( p_v^{\text{even}} \). At each interaction, both lists are updated. However, whenever we reach an interaction \( r \) whose order is a multiple of \( W \), we reset either \( p_v^{\text{odd}} \) or \( p_v^{\text{even}} \) as follows. If the order of \( r \) in the sequence \( R \) of interactions is an odd multiple of \( W \), for each vertex \( v \in V \), we reset its provenance list \( p_v^{\text{odd}} \) by setting \( p_v^{\text{odd}} = \{(\alpha, |B_v|)\} \), where \( \alpha \) is an artificial vertex, representing the entire set \( V \) of vertices. This means that we assume that the entire quantity in \( B_v \) has unknown provenance. If the order of \( r \) is an even multiple of \( W \), for all vertices \( v \), we reset \( p_v^{\text{even}} \) by setting \( p_v^{\text{even}} = \{(\alpha, |B_v|)\} \). After any interaction \( r \), we can track provenance for any vertex \( v \) using whichever of \( p_v^{\text{even}} \) or \( p_v^{\text{odd}} \) was last recently reset. This guarantees that we can track the provenance of quantities born at least \( W \) (and at most \( 2 \cdot W \)) interactions before. The space requirements (i.e., the total space required to store the provenance lists) are now controlled due to the provenance list resets.

Figure 4 illustrates how, for each vertex \( v \), \( p_v^{\text{odd}} \) and \( p_v^{\text{even}} \) are updated and used. Assuming that \( W = 100 \), until the 100-th interaction, \( p_v^{\text{odd}} \) and \( p_v^{\text{even}} \) are identical and either of them can be used. Since \( p_v^{\text{odd}} \) is reset at the 100-th interaction, between the 100-th and the 200-th interaction \( p_v^{\text{even}} \) is used to track the provenance of quantities which were generated since the first interaction. Similarly, between the 200-th and the 300-th interaction \( p_v^{\text{odd}} \) is used to track provenance up to the 100-th interaction.

![Figure 4: Windowing approach in provenance tracking](image-url)
5.3.2 Budget-based provenance. Another approach which we can apply to control the memory requirements and make proportional provenance tracking feasible on large graphs is to allocate a maximum capacity $C$ (budget) to each vertex $v$ for its provenance list $p_v$. Whenever we have to add new entries to $p_v$, if the required capacity after the addition exceeds $C$, we select a certain fraction $f$ of entries to keep in $p_v$. We remove the remaining entries and assume that the total quantity $Q$ which originates from them was born at an artificial vertex $a$, modeling all vertices (i.e., unknown source). Hence, if $p_v$ includes an $(a,q)$ entry, the entry is updated to $(a,q+Q)$; if not, a new entry $(a,Q)$ is added to $p_v$.

With this approach, the space requirements of proportional provenance tracking become $O(|V| \cdot C)$. The larger the value of $C$ the more accurate provenance tracking becomes. Parameter $f$ should be chosen such that the memory allocated at each vertex is not underutilized and, at the same time, shrinking does not happen very often. We suggest a value between 0.6 and 0.8. Finally, the selection of entries to keep when the budget $C$ is reached in $p_v$ can be done using different criteria. For example, we can keep the entries with the largest quantities, or set a priority/importance order to vertices and keep provenance data for the most important ones.

As an example, assume that $p_v = \{(x,1), (u,3), (w,2), (z,1)\}$ and let $C = 5$. Let $\{(x,2), (w,1), (y,4)\}$ be the new entries that have to be added/merged into $p_v$. After the change, $p_v$ should become $p_v = \{(x,1), (u,3), (w,3), (x,2), (y,4), (z,1)\}$, i.e., the capacity constraint $C = 5$ is violated. If $f = 0.6$, we should keep $0.6 \cdot C = 3$ entries; let us assume that we keep the ones with the largest quantities, i.e., $\{(u,3), (w,3), (y,4)\}$. The remaining three entries are replaced in $p_v$ by an entry $(a,4)$, since the sum of their quantities is 4. Hence, after the update, $p_v$ becomes $\{(u,3), (w,3), (y,4), (a,4)\}$. Note that selecting the entries with the largest quantities may cause a bias in favor of origins that generate quantities early over origins whose generation is spread more evenly in the timeline.

6 TRACKING THE PATHS

So far, we have studied the problem of identifying the origins of the quantities accumulated at the vertices. An additional question is which path did each of the quantities, accumulated at a vertex $v$, follow from its origin to $v$. This information can provide more detailed explanation for the reasons behind data transfers and corresponds to how-provenance in query evaluation [9].

To implement how-provenance for the selection models of Sections 4.1 and 4.2, for each quantity element in the buffer $B_v$ of every node $v$, we maintain a transfer path, which captures the route that the element has followed so far from its origin to $v$. When a new quantity element is generated, either as a result of a split (i.e., Line 10 of Algorithm 2), or anew (i.e., Line 20 of Algorithm 2), its path is initialized to include just the origin vertex $r.s$. Every time a quantity element is transferred from one vertex to another as a result of an interaction $r'$ (i.e., Line 14 of Algorithm 2), its path is extended to include the transmitter vertex $r'.s$. This way, for each quantity element, we keep track of not just its origin but also the path which the quantity has followed.

Note that path tracking in the case of proportional selection is not meaningful, because, if $r.q < |B_{r.s}|$, all quantities in $B_{r.s}$ are split to a fraction that remains at $B_{r,s}$ and a fraction that moves to $B_{r',s}$, wherein they are combined with the corresponding quantities from the same origins. This means that quantities in a buffer from the same origin (but potentially from multiple different paths) are mixed and indistinguishable.

Complexity Analysis Path tracking does not change the time complexity, as the number of path changes is $O(|R|)$ and each path initialization or extension costs $O(1)$. On the other hand, the space complexity increases by a factor of $O(|R|/|V|)$, i.e., the expected number of quantity element transfers (executions of Line 14 of Algorithm 2). Hence, the time complexity increases to $O(|R|^2/|V|)$.

7 EXPERIMENTAL EVALUATION

In this section, we experimentally evaluate the performance and scalability of our proposed provenance tracking techniques, which apply to the different selection models presented in Section 4. For this, we used five real TINs, described in Section 7.1. We compare the different selection policies for information propagation in terms of runtime cost and memory requirements in Section 7.2. In Section 7.3, we evaluate the performance of selective and grouped provenance tracking using the proportional selection policy. Section 7.4 tests the windowing and budget-based approaches for limiting the scope of provenance tracking. Section 7.5 evaluates the memory and computational overheads of tracking the paths of quantities accumulated at each vertex. Finally, Section 7.6 presents a use case that demonstrates the practicality of provenance in TINs. All provenance tracking methods were implemented in C and compiled using gcc with -O3 flag. The experiments were run on a machine with a 3.6GHz Intel i9-10850k processor and 32GB RAM.

7.1 Description of datasets

Table 6 summarizes the statistics for each of the datasets that we use in the experiments. Below, we provide a detailed description for each of them.

**Bitcoin Network:** This dataset includes all transactions in the bitcoin network up to 2013.12.28; we considered these transactions as interactions. The data were preprocessed and made available by the authors of [26]. We merged bitcoin addresses which belong to the same user. For each interaction, as quantity, we consider the corresponding amount of BTCs exchanged between the addresses. We converted all amounts to BTC (originally Satoshi) and we did not take into consideration transactions with insignificant flow (i.e., less than 0.0001 BTC). Data provenance in this network can unveil the funding sources of addresses and explain the reasons behind bitcoin exchanges.

**CTU Network:** A Botnet traffic network was extracted and created by CTU University [14]. We used the data and we designed a TIN. The vertices are the IP addresses and the interactions are the transactions among the nodes at different time periods. The quantity of each interaction is the total amount of bytes which are transferred between the corresponding vertices. Tracing the provenance of quantities that reach vertices in such a network may help toward analysis of potential network attacks.

**Prosper Loans:** We downloaded this dataset from http://konect.cc and created the corresponding interaction network. The vertices of the network correspond to users and the interactions represent...
loans between them. The lend amounts are the quantities that are exchanged at the interactions. Tracking the provenance of amounts that reach certain nodes may help in the identification of the direct or indirect relationships between lenders and borrowers.

**Flights Network:** We extracted flights data from Kaggle\(^3\). We converted the original file into an interaction network, where vertices are the origin and destination airports and the time of departure was used to model the time of the corresponding interaction. We used the number of passengers in each flight as the quantity in the corresponding interaction. Since this number was not given in the original data, we have put a random number between 50 and 200. Provenance information can help us understand the reasons behind potential traffic bottlenecks, or other issues at airports.

**Taxis Network:** We considered NYC yellow taxi trips\(^4\) on January 1st 2019 as interactions in a TIN, where vertices are taxi zones (pickup and drop-off districts), the drop-off time represents the time of interactions and the number of passengers are the corresponding quantities. Similar to the flights network, we can apply provenance tracking to investigate the reasons behind the accumulation of passengers at different zones.

| Dataset     | #nodes | #interactions | average r.q. |
|-------------|--------|---------------|--------------|
| Bitcoin     | 12M    | 45.5M         | 34.4B        |
| CTU         | 608K   | 2.8M          | 19.2kB       |
| Prosper Loans | 100K   | 3.08M         | 876          |
| Flights     | 629    | 5.7M          | 125          |
| Taxis       | 255    | 231K          | 1.53         |

### 7.2 Provenance tracking performance

In our first set of experiments, we investigate the runtime cost and the memory requirements of provenance tracking based on the different selection policies for information propagation, presented in Section 4. We executed each method by processing the entire sequence of interactions and updating the necessary information for each of them, according to the algorithms described in Section 4. Tables 7 and 8 show the runtime cost and the peak memory use by the different selection policies. As a point of reference we also included the basic propagation algorithm that does not track provenance (Algorithm 1), denoted by NoProv.

The two tables, we observe that the methods based on generation time (Section 4.1) are scalable, since they terminate even at very large graphs with millions of interactions (i.e., Bitcoin network). Naturally, they are one to two orders of magnitude slower than NoProv, as NoProv has $O(1)$ cost per interaction. Their space overhead compared to NoProv is not high for big and sparse graphs, like Bitcoin and CTU. On the other hand, for smaller graphs with heavy traffic between vertices, the space requirements become high.

The methods that select the information to propagate based on order of receipt (Section 4.2) are also slower than NoProv, but faster than the ones that use generation time, because they do not have to maintain a heap and select the propagated quantities from it. Instead, the simpler data structures that they use (stack, FIFO queue) are more efficient. In terms of space, their requirements are lower compared to the order-of-receipt policies mainly because they do not need to store and propagate the time of birth together with the origin vertices (i.e., each provenance tuple has two values instead of three). Their behavior in big/sparse graphs compared to small/dense ones is similar to the one of order-of-receipt policies discussed above.

As opposed to the selection policies of Sections 4.1 and 4.2, the proportional selection policy, presented in Section 4.3, performs best when the number of vertices in the graph is small (i.e., at the Flights and Taxis networks). This is expected because their storage overhead in this case is manageable (at most $O(|V|^2)$). Specifically, the proportional policy using dense vector representations can be used only for the Flights and Taxis networks, with very good performance. Even when the sparse vector representations are used, the required memory exceeds the capacity of our machine in the Bitcoin and CTU networks. This approach can be used on the Prosper Loans network, however, it requires a lot of space (2.4GB) and it is significantly slower than the policies of Sections 4.1 and 4.2, because it needs to manage and maintain long lists. This necessitates the use of the scope limiting techniques described in Section 5.3, as tracking provenance from all vertices in the entire history of interactions becomes infeasible.

### 7.3 Selective and grouped provenance

In the next set of experiments, we evaluate the performance of proportional provenance only for a subset of vertices or for groups of vertices as described in Sections 5.1 and 5.2. We conduct the experiments on the three largest networks (in terms of number of vertices), i.e., Bitcoin, CTU, and Prosper Loans. Recall that on these networks tracking proportional provenance from all vertices is infeasible or very expensive. Let $k$ denote the number of selected vertices (for selective provenance) or the number of groups (for grouped provenance). We measure the runtime cost and memory requirements of proportional provenance for different values of $k$. In the case of selective provenance, we select the top-$k$ contributing vertices as the set of vertices for which we will measure provenance. That is, we first run NoProv (Algorithm 1) and measure the total quantity generated by each vertex and then choose the ones that generate the largest quantity. In case of grouped provenance, we randomly allocate vertices to groups in a round-robin fashion; since the runtime performance and memory requirements are not affected by the group sizes or the way the vertices are allocated to groups, this allocation does not affect the experimental results.

Figure 5 shows the runtime performance (in sec.) and memory requirements (in MB) for the different values of $k$ on the different datasets. As expected the runtime and the memory requirements are roughly proportional to $k$. For small values of $k$ (less than 20) the runtime is roughly constant with respect to $k$ (see Figure 5(a)). This is because of the effect of SIMD instructions, which make vector operations (lines 9 and 10 of Algorithm 3) unaffected by the vector size. SIMD data parallelism is already in full action for values of $k$ greater than 20, so we observe linear scalability from thereon.

Figure 5: Selective and grouped proportional provenance

7.4 Limiting the scope of provenance tracking

As shown in Section 7.2, proportional provenance tracking throughout the entire history of interactions is infeasible, due to its high memory requirements. In addition, keeping and updating sparse representations of provenance vectors becomes expensive over time as the lists grow larger because of the higher cost of merging operations.

Figure 6 verifies this assertion, by showing the cumulative time and memory requirements while tracking proportional selection after each interaction for the first 500K interactions in Bitcoin and CTU (after this point, the memory requirements become too high), and for all interactions in Prosper Loans. Observe that the cumulative runtime increases superlinearly with the number of interactions and so do the memory requirements (these two are correlated). The average cost for handling each interaction grows as the number of processed interactions increases, which is attributed to the population of the sparse lists that keep the provenance information for each vertex; merging operations on these lists become expensive as they grow.

We now evaluate the solutions proposed in Section 5.3 for limiting the scope of provenance tracking in order to make the maintenance of proportional provenance vectors feasible for large graphs. Once again, we experimented with the three largest networks and applied the two approaches proposed in Section 5.3 on them. Figure 7 shows the runtime cost and the memory requirements of the windowing approach for different values of the window parameter $W$. As the figure shows, by increasing the size of the window, we improve the runtime performance as the buffers have to be reset less frequently. On the other hand, increasing the window size naturally increases the memory requirements. For Bitcoin and Prosper Loans, larger window sizes are affordable, as the memory requirements do not increase a lot. On the other hand, for CTU the memory requirements almost double when $W$ doubles. In summary, the windowing technique is very useful, especially when we want to have guaranteed accurate provenance information for all vertices up to a time window in the past.

Figure 8 shows the runtime cost and the memory requirements of the budget-based approach for different values of the maximum budget $C$ given as capacity for provenance entries to each vertex. As the figure shows, by increasing the budget $C$ per vertex, the runtime cost to maintain provenance increases, as the provenance information at buffers becomes larger and merging lists becomes more expensive. The increase in the runtime cost is not very high though, because many lists remain relatively short and the number of list shrinks are less frequent. At the same time, the space requirements grow linearly with $C$, which means that very large values of $C$ are not affordable for large graphs like Bitcoin.
Figure 6: Cumulative time vs. number of processed interactions

Figure 7: Windowing approach

Figure 8: Budget-based provenance

In order to assess the value of this approach, in Table 9, we measured for each of the three large datasets and for different values of $C$, (i) the number of times each non-empty buffer has been shrunk and (ii) the percentage of vertices (with non-empty buffer) whose buffer was shrunk at least once. Especially for the larger networks with high memory requirements (Bitcoin and CTU), we observe that the number of shrinks and the percentage of vertices where they take place converge to low values and, after some point, increasing $C$ does not offer much benefit. Overall, the budget-based approach is attractive since each buffer is shrunk only a few times on average, meaning that the provenance information loss is limited even in large graphs. For example, at the Bitcoin network, for a value of

---

3We could not use values of $C$ larger than 100 on Bitcoin due to memory constraints.
C = 50, each buffer is shrunk 1.5 times on average after 45M interactions, meaning that each buffer tracks provenance information that traces back to tens of millions of transactions before.

### Table 9: Shrinking statistics in budget-based provenance

|          | Bitcoin Network | CTU Network | Prosper Loans Network |
|----------|-----------------|-------------|-----------------------|
| C        | avg. shrinks    | % vertices  | avg. shrinks          | % vertices  | avg. shrinks    | % vertices  |
| 10       | 1.94            | 18.38       | 7.27                  | 31.07       | 20.67          | 94.7        |
| 50       | 1.51            | 14.79       | 5.1                   | 28.68       | 4.77           | 79.29       |
| 100      | 1.43            | 14.21       | 4.77                  | 27.94       | 2.97           | 69.09       |
| 200      | – –             | – –         | 4.53                  | 26.6        | 2.1            | 59.16       |
| 500      | – –             | – –         | 4.34                  | 25.24       | 1.5            | 47.64       |
| 1000     | – –             | – –         | 4.3                   | 25.02       | 1.23           | 41.39       |

#### 7.5 Path tracking

As discussed in Section 6, it might be desirable, for each quantity that has reached the buffer of a vertex to know not just the vertex that generated the quantity, but also the path that the quantity followed in the graph until it reached its destination. In the next experiment, we evaluate the overhead of tracking the paths (i.e., *how*-provenance) compared to just tracking the origins of the quantities. We implemented path tracking as part of the LIFO selection policy for provenance (Section 4.2) and used it to track the paths for all (origin, quantity) pairs accumulated at vertices after processing all interactions in all datasets. Table 10 shows the runtime performance, the memory requirements, and the average path length for each quantity element. The memory requirements are split into the memory required to store the provenance entries in the lists (as in LIFO) and the memory required to store the paths. Observe that for most datasets the memory overhead for keeping the paths is not extremely high. This overhead is determined by the average path length (last column of the table), which is relatively low in four out of the five datasets. Only in Flights the storage overhead for the paths is very high because quantities travel a long way. In this dataset, the number of vertices is very small compared to the number of interactions, so we can expect very long paths. Still, on all datasets, the runtime is only up to a few times higher compared to tracking just the origins and not the paths (see Table 7, column LIFO), meaning that path tracking is feasible even for very long sequences of interactions on large graphs, like Bitcoin.

### Table 10: Tracking provenance paths in LIFO

| Dataset | time (sec) | mem entries (MB) | mem paths (MB) | total mem (MB) | avg. path length |
|---------|------------|------------------|----------------|----------------|-----------------|
| Bitcoin | 2.36       | 354.62           | 847.56         | 1202.19        | 4.75            |
| CTU     | 0.36       | 33.87            | 7.16           | 41.03          | 0.63            |
| Prosper | 0.4        | 36.85            | 0.74           | 37.59          | 0.06            |
| Flights | 0.17       | 0.62             | 57.09          | 57.72          | 273.17          |
| Taxis   | 0.088      | 0.58             | 1.09           | 1.68           | 5.55            |

#### 7.6 Use case

Figure 9 demonstrates a practical example of provenance tracing in TINs. The plot shows the total accumulated quantities at the vertices of Bitcoin after each interaction (first 100K interactions, proportional selection policy). Consider a data analyst who wants to be alerted whenever a vertex $v$ accumulates a significant amount of money, which does not originate from $v$’s direct neighbors (i.e., $v$’s neighbors just relay amounts to $v$). Hence, after each interaction, we issue an alert when the receiving vertex does not have any quantity that originates from its neighbors and the total quantity in its buffer exceeds 10K BTC. The colored dots in the figure show these alerts (89 in total) and provenance information for some of them. Red dots are alerts where the number of contributing vertices is less than five (the rest of them are blue). We observe that in most cases the amount was received from numerous vertices (an indication of possible “smurfing”). This alerting mechanism is very efficient and easy to implement, as we only have to maintain at each vertex $v$ the total quantity that originates from vertices that transfer quantities to $v$ (i.e., direct neighbors of $v$).

#### 8 Conclusions

In this paper, we introduced and studied provenance in temporal interaction networks (TINs). To the best of our knowledge, we are the first to define and study this problem, considering the data transfers among the vertices, as interactions take place over time. We investigate different selection policies for data propagation in TINs that correspond to different application scenarios. For each policy, we propose propagation mechanisms for provenance (annotation) data and analyze their space and time complexities. For the hardest policy (proportional selection), we propose to track provenance from a limited set of vertices or from groups thereof. We also propose to limit provenance tracking up to a sliding window of past interactions or to set a space budget at each vertex for provenance tracking. We evaluated our methods using five real datasets and demonstrated their scalability. In the future, we plan to investigate lazy approaches for data provenance in TINs (e.g., apply the replay lazy [16] approach, or investigate backtracing methods). In addition, we plan to study whether our approaches for TINs can be adapted to be applied on social networks, where data are diffused, instead on being relayed from vertex to vertex. Finally, we plan to analyze in depth the computed provenance data in TINs, with the help of data mining approaches, in order find interesting insights in them.
