Did JWST observe imprints of axion miniclusters or primordial black holes?

The James Webb Space Telescope has detected surprisingly luminous early galaxies that indicate a tension with the ΛCDM. Motivated by scenarios including axion miniclusters or primordial black holes, we consider power-law modifications of the matter power spectrum. We show that the tension could be resolved if dark matter consists of compact heavy \(10^{-11} \text{M}_\odot\) dark matter (DM) halos at high redshifts \(z > 9\) have been already proposed. These proposals include heavy primordial black holes (PBHs) [17], non-Gaussianities in primordial fluctuations [18], and modified dark energy equation of state [19].

In this paper, we focus on scenarios, including axion miniclusters or heavy PBHs, which boost the matter power spectrum at \(k > 3 \text{hMpc}^{-1}\). Our analysis uses extreme value statistics (EVS) [20, 21] and considers two of the most extremal galaxies observed so far by JWST: CEERS-1749 of stellar mass log\(_{10}(M_*/\text{M}_\odot) = 9.6 \pm 0.2\) at redshift \(z = 16 \pm 0.6\) [2] and Galaxy 14924 of stellar mass log\(_{10}(M_*/\text{M}_\odot) = 10.9 \pm 0.3\) at redshift \(z = 9.9 \pm 0.5\) [3].

II. MATTER POWER SPECTRUM

The matter power spectrum is strictly constrained at scales \(k \lesssim 3 \text{hMpc}^{-1}\) by measurements of galaxy clustering, Lyman-alpha forest data and the UV luminosity function [22–24]. The latter is obtained using data from the HST and will improve with the JWST observations [25, 26]. These observations agree well with the predictions of the standard ΛCDM model. At smaller scales, significant deviations from the CDM matter power spectrum are possible and affect the abundance of \(M \lesssim 10^{11} \text{M}_\odot\) halos. In particular, a matter power spectrum that exceeds the ΛCDM prediction at scales \(O(10) \text{hMpc}^{-1}\) gives rise to an increased abundance of massive early galaxies, perhaps being compatible with the JWST observations.

We consider power-law modifications to the matter power spectrum at small scales:

\[
P(k) = P_{\text{CDM}}(k) + P_{\text{CDM}}(k_c) \left( \frac{k}{k_c} \right)^n,
\]

where \(P_{\text{CDM}}(k)\) denotes the standard ΛCDM matter...
FIG. 1. The matter power spectrum for standard ΛCDM (black dashed) and for three values of \( k_c \) with \( n = 0 \) (solid) and \( n = 1 \) (dashed). The points with errors correspond to SDSS measurements of galaxy clustering from luminous red galaxies (purple) [22] and Lyman-α forest (black) [23] and HST measurements of UV luminosity function (blue) [24]. The blue dashed curve shows the maximal cut-off scale for \( k^4 \) growth of the adiabatic curvature power spectrum from COBE/Firas bound on \( \mu \) and \( y \) distortions [27].

power spectrum, \( k_c > 3h\text{Mpc}^{-1} \) the scale above which the power-law behaviour takes over and \( n \) the spectral index of the power-law. The power-law part is cut at some scale \( k_{\text{cut}} > k_c \). As discussed later, our results are insensitive to the exact value as long as \( k_{\text{cut}} \gg 30h\text{Mpc}^{-1} \). For the CDM matter power spectrum we consider a nearly scale-invariant curvature power spectrum with the spectral index \( n_s = 0.96 \) and the fitted transfer function from Ref. [28]. In Fig. 1 we show the CDM matter power spectrum and examples of the modified matter power spectra (1) together with the constraints from measurements of galaxy clustering [22], Lyman-alpha forest data [23] and UV luminosity function [24].

Deviations of the form of Eq. (1) from the standard ΛCDM matter power spectrum can arise, for example, in the following scenarios:

1. In axion-like particle DM models, in which the global \( U(1) \) symmetry is broken after the cosmic inflation, large amplitude small-scale fluctuations are generated via the Kibble mechanism leading to the formation of axion miniclusters [29]. This corresponds to an \( n = 0 \) contribution to the matter power spectrum with an amplitude [30–34]

\[
A = \frac{4}{5} \frac{6\pi^2}{D(z_{\text{eq}})^2} k_{\text{cut}}^{-3},
\]

where \( D(z_{\text{eq}}) \) denotes the growth factor (normalized so that \( D(0) = 1 \)) at matter-radiation equality and \( k_{\text{cut}} \) the cut-off given by the scale that entered the horizon at the moment when the axion of mass \( m_a \) began to oscillate (i.e., \( 3H = m_a \) at \( aH = k_{\text{cut}} \)).

\[
k_{\text{cut}} \simeq 300\text{Mpc}^{-1} \sqrt{\frac{m_a}{10^{-18} \text{eV}}},
\]

Using a power law approximation for \( P_{\text{CDM}} \) around \( k_c = O(10)h\text{Mpc}^{-1} \), we find that the scale \( k_c \), at which \( P_{\text{CDM}}(k_c) = A \), is given by

\[
k_c \approx 3h\text{Mpc}^{-1} \left( \frac{m_a}{10^{-18} \text{eV}} \right)^{0.6},
\]

thus \( k_{\text{cut}} \gg k_c \) is satisfied in the relevant \( k_c \) range.

2. In models with heavy PBHs the graininess associated with the discrete Poisson distribution of PBHs [35, 36] or PBH clusters [37] (but possibly also other compact structures) generates an \( n = 0 \) contribution to the matter power spectrum with an amplitude [38, 39]

\[
A = \frac{1}{n_{\text{PBH}}} \frac{f_{\text{PBH}}^2}{D(z_{\text{eq}})^2} = \frac{6\pi^2 f_{\text{PBH}}^2}{D(z_{\text{eq}})^2} k_{\text{cut}}^{-3},
\]

where \( f_{\text{PBH}} \) denotes the fraction of DM in PBHs, \( m_{\text{PBH}} \) the PBH mass and \( \rho_{\text{DM}} \) the DM density. The cut-off scale of the spectrum is given by the average separation of PBHs,

\[
k_{\text{cut}} \simeq (6\pi^2 n_{\text{PBH}})^{1/3} = 900h\text{Mpc}^{-1} \left( \frac{f_{\text{PBH}} 10^4 M_{\odot}}{m_{\text{PBH}}} \right)^{1/3}.
\]

Below this scale, one expects a single PBH in the volume of the corresponding comoving sphere and thus the seed effect [35, 36, 40–42] begins to dominate over the Poisson one.\(^2\) The scale \( k_c \) is

\[
k_c \approx 6h\text{Mpc}^{-1} \left( \frac{f_{\text{PBH}} m_{\text{PBH}}}{10^4 M_{\odot}} \right)^{-0.4}.
\]

As Eq. (4), the latter approximation works well at \( k_c = O(10)h\text{Mpc}^{-1} \). We find that \( k_c < k_{\text{cut}} \) if \( f_{\text{PBH}} > 10^{-4} (m_{\text{PBH}}/10^4 M_{\odot})^{-0.09} \). Because CMB observations constrain \( f_{\text{PBH}} < 10^{-8} \) for \( m_{\text{PBH}} \gtrsim 10^4 M_{\odot} \) [43],\(^3\) explanations for the JWST observations relying on the Poisson effect from heavy PBHs are not viable. However, the accretion constraint can be softened if lighter PBHs were formed in dense clusters (as described e.g. in [45–49]) with masses above \( 10^3 M_{\odot} \). Such clusters

\(^1\) We assume, for simplicity, that the axion mass is temperature independent. For further discussion, see e.g. Refs. [30, 33].

\(^2\) Importantly, the usual Press-Schechter formalism breaks down above \( k_{\text{cut}} \) as the fluctuations in the PBH density are non-Gaussian. Note that the scale at which the PBH-induced density fluctuations become non-linear, \( k_{\text{cut},NL} \approx \left( n_{\text{PBH}}/f_{\text{PBH}} \right)^{1/3} \gg k_{\text{cut}} \) is smaller.

\(^3\) For a review on constraints on PBHs, see e.g. [44].
would then act as sources for the Poisson fluctuations instead of the individual PBHs [37].

We must stress that here we focused on the Poisson effect. As massive BHs may play an important role in the formation of the first galaxies [50], we cannot rule out the so-called seed effect from PBHs with $f_{PBH} \lesssim 10^{-8}$ as a potential explanation. Assuming a monochromatic mass distribution, the expected number of PBHs of initial mass $M_{PBH}$ in the JWST light cone (see Eq. (13)) at redshifts $15 < z < 17$ is

$$N_{PBH,15<z<17} = 2.8 \times \left( \frac{f_{PBH}}{10^{-8}} \right) \left( \frac{M_{PBH}}{10^8 M_\odot} \right)^{-1}. \quad (8)$$

However, the number of massive PBHs cannot be straightforwardly translated into the number of luminous galaxies (such as CEERS-1749). Due to its non-linear nature and dependence on uncertain baryonic physics, the PBH seed scenario requires a dedicated study.

3. Enhanced adiabatic power spectra can be generated, for example, in single field inflation if the inflaton potential has features which slow down the inflaton field [51–53]. Such scenarios are relevant for PBH formation [54, 55] and are thus mostly studied in that context. However, they could be realized without any relation to PBHs. In typical models of single-field inflation, a curvature power spectrum with a constant spectral index $n_s = 1$ can be realized in inflationary scenarios with increasing features [58]. In the following, we consider at most $n = 1$.

In the first two cases, the power-law contribution to the matter power spectrum constitutes an isocurvature component to the matter fluctuations. The COBE/Firas constraint shown in Fig. 1 applies to the adiabatic component, while the constraint from $\mu$ and $y$ distortions on the isocurvature component is much weaker [27]. In particular, the cut-off scales in the first two scenarios are far below that constraint.

In the third case, the fluctuations are adiabatic, and the COBE/Firas constraint excludes PBH formation if $k_c \lesssim 10^2 h$Mpc$^{-1}$ unless the growth of the curvature power spectrum is relatively slow, less than $\propto k^3$, which translates to $n < 0$ in Eq. (1). However, steep growth of the curvature power spectrum at scales $k_c = O(10) h$Mpc$^{-1}$ that terminates with amplitude less than four orders of magnitude above the CMB amplitude is not excluded.

![FIG. 2. The halo mass function for the matter power spectra shown in Fig. 1 at redshifts $z = 15$ and $z = 0$. The thin line shows the CDM halo mass function at $z = 0$.](image)

III. HALO MASS FUNCTION

The halo mass function can be expressed as

$$\frac{dn}{d \ln M} = \frac{\rho_m}{M} \nu f(\nu) \frac{d \ln \nu}{d \ln M},$$

where $\rho_m$ denotes the average present mass density and $\nu \equiv \delta_c(z)^2/\sigma_M^2$. The critical overdensity required for collapse is $\delta_c(z) = 1.686/D(z)$, where $D(z)$ is the growth factor $[59].$

$$D(z) \propto H(z) \int_z^\infty \frac{dz'}{H(z')} \frac{(1+z')}{(1+z)k_c^2}, \quad (10)$$

normalized such that $D(0) = 1$. In the Press-Schechter formalism [60] with corrections from ellipsoidal dynamics [61]

$$\nu f(\nu) = A \left[ 1 + (q\nu)^{-p} \right] \sqrt{\frac{q\nu}{2\pi}} e^{-q\nu/2}, \quad (11)$$

where $p = 0.30$, $A = 0.322$ and $q = 0.75$ [62]. The variance $\sigma_M^2$ at the mass scale $M$ is

$$\sigma_M^2 = \frac{1}{2\pi^2} \int dk k^2 P(k)W^2(kR) |_{R=R(M)},$$

and the comoving smoothing scale $R$ is related to the halo mass by $M = 4\pi\rho_m R^3/3$. We use a real space top-hat window function $W(x) = 3(\sin x - x \cos x)/x^3$.

In Fig. 2 we show the halo mass function corresponding to the modified power spectra shown in Fig. 1. We see that the deviation of the halo mass function from the standard $\Lambda$CDM prediction at the relevant scales depends mostly on the slope $n$. This

$^4$ This growth factor is for adiabatic fluctuations. While it is slightly different for isocurvature fluctuations [38], we find that this does not make a significant difference in our results.
indicates that the exact shape of the modification in $P$ has a relatively minor impact on our results and that the two-parameter model (1) is sufficient to capture the relevant qualitative features. Moreover, we find that the halo mass function at the relevant mass scales does not significantly depend on the cut-off scale of the power-law part as long as $k_{\text{cut}} \gtrsim 30 h^{-1}\text{Mpc}$.

IV. ANALYSIS AND RESULTS

The expected number of halos in the mass range $M_{\text{min}} < M < M_{\text{max}}$ observed in the redshift range $z_{\text{min}} < z < z_{\text{max}}$ is given by the light-cone integral

$$N = f_{\text{sky}} \int_{z_{\text{min}}}^{z_{\text{max}}} \frac{dV}{dz} \int_{M_{\text{min}}}^{M_{\text{max}}} dM \frac{dn}{dM},$$

(13)

where $f_{\text{sky}}$ is the fraction of the sky being observed and $V_c$ is the comoving Hubble volume at redshift $z$. For the JWST observations, the relevant quantity is the stellar mass of the halo, related to the halo mass $M$ via [12]

$$M_* = f_* f_b M,$$

(14)

where $0 < f_* < 1$ is the star formation efficiency and $f_b \approx \Omega_b/\Omega_m \approx 0.16$ is the fraction of all matter in baryons. For example, taking the CDM halo mass function and a typical optimistic efficiency according to lower redshift observations $f_* = 0.1$ [63], we find that the expected number of halos similar to CEERS-1749 whose stellar mass is $M_* > 10^{9.6} M_\odot$ at redshift $z > 15$ within $f_{\text{sky}} = 40 \text{arcmin}^2$ is $N \approx 7 \times 10^{-8}$.

To compute the distribution of the heaviest halo expected to be seen in an observed light-cone volume we utilize EVS [64, 65]. The EVS probability density function (PDF) in the full mass range $0 < M < \infty$ is [64]

$$\Phi(M) = N f(M) F(M)^{N-1},$$

(15)

where

$$f(M) \propto \int_{z_{\text{min}}}^{z_{\text{max}}} \frac{dV}{dz} \frac{dn}{dM}, \quad F(M) = \int_0^M dM' f(M'),$$

(16)

are the normalized PDFs of halo masses within the redshift range $z_{\text{min}} < z < z_{\text{max}}$ and the corresponding cumulative distribution.

In Fig. 3, we show the $1\sigma$ and $2\sigma$ confidence intervals of the EVS PDF as a function of $k_c$ for $f_{\text{sky}} = 2.7 \times 10^{-7}$ and $z > 15$. As expected, the distribution prefers larger stellar masses at smaller $k_c$. Moreover, the mean of the EVS distribution deviates by less than $10\%$ from the $M_*$ value corresponding to $N(M > M_*/f_* f_b, z > 15) = 1$ within $f_{\text{sky}} = 2.7 \times 10^{-7}$.

The final results of our analysis are summarized in Fig. 4. The green bands show the $1\sigma$ and $2\sigma$ ranges in $k_c$ computed from the likelihood

$$\int dM \Phi(M) p(M|M_c),$$

(17)

assuming a log-normal distribution, $p(M|M_c) = \exp[-\ln(M/M_c)/2\sigma^2]/\sqrt{2\pi}\sigma^2$, for the measured mass $M_c$. The left panels show these ranges for CEERS-1749 and the right panels for Galaxy 14924. We find that a significantly enhanced star formation efficiency and a modification over the CDM matter power spectrum at scales $k_c = O(10) h^{-1}\text{Mpc}$ would be required to alleviate the tension below the $2\sigma$ level. A high star formation efficiency may lead to tensions with the CMB measurements.

---

5 Even though the widely used condition $N = 1$ provides a reasonably accurate mass scale it does not provide similarly evident treatment for the accompanying stochasticity. This is the main reason to use EVS, which equips us with a complete statistical framework.

6 The dominant UV luminosity function constraint $a_\alpha = 0.66^{+0.43}_{-0.17}$ in Ref. [24] is given for the relative enhancement over the $\Lambda$CDM in the bin $0.5 \text{Mpc}^{-1} \leq k < 2.25 \text{Mpc}^{-1}$. As the constraint depends non-trivially on the shape of the power spectrum and has not been computed for the parametrization (1), we estimate the corresponding constraint on $k_c$ by comparing the amplitude relative to the $\Lambda$CDM at the lower edge of the bin, $k = 0.5 \text{Mpc}^{-1}$.
FIG. 4. The green bands indicate the 1σ and 2σ confidence intervals of the likelihood averaged over the EVS PDF. The left panels are for the stellar mass estimate of CEERS-1749 at \( z > 15 \) and the right panels are for the stellar mass estimate of Galaxy 14924 at \( z > 9 \).

of reionization history [14]. The lowest \( f_\star \), still compatible with both the Lyman-\( \alpha \) and UV luminosity function constraints at the 2σ confidence level, is obtained for \( k_c = 50h\text{Mpc}^{-1} \). This can be reached if

1. DM consists of axions of mass \( m_a \approx 2 \times 10^{-18} \text{eV} \) and the Peccei-Quinn symmetry is broken after inflation so that axion miniclusters are formed. The mass range \( 10^{-19} \text{eV} \lesssim m_a \lesssim 10^{-16} \text{eV} \) is, however, potentially excluded by black hole superradiance\(^7\) and the observed spins of superheavy black holes [67–69]. For \( m_a > 10^{-16} \text{eV} \) we get \( k_c > 50h\text{Mpc}^{-1} \), which does not affect the halo mass function at the relevant scales.

2. a fraction \( f_{\text{PBH}} > 0.005 \) of DM consists of PBHs or PBH clusters of mass \( m_{\text{PBH}} \approx 4 \times 10^6 M_\odot (f_{\text{PBH}}/0.005)^{-1} \). However, accretion constraints [43] exclude the explanation from the Poisson effect from uniformly distributed individual PBHs, but the explanation with heavy clusters of subsolar mass PBHs may be viable.

3. the curvature power spectrum grows steeply at \( 4h\text{Mpc}^{-1} \) and the growth terminates before the COBE/Firas bound. This case is possible though not well motivated. In particular, it is non-trivial to realize such growth at those scales while simultaneously remaining in agreement with the CMB constraints.

V. CONCLUSIONS

We have performed a careful analysis of whether a modified matter power spectrum could explain the existence of two of the most extreme galaxies observed so far by JWST, CEERS-1749 and Galaxy 14924. Considering power-law modifications to the matter power spectrum and extreme value statistics, we have estimated the distribution of the heaviest galaxies expected to be seen by JWST above a given redshift. We have found that both a high star formation efficiency and a modification of the matter power spectrum at the smallest scales allowed by the Lyman-\( \alpha \) and UV luminosity function constraints are

\(^7\) The constraints can be alleviated in self-interacting scenario where the superradiant growth of the axionic cloud may be suppressed [66].
needed for this distribution to be compatible with the observed stellar mass, in particular for Galaxy 14924.

We have shown that extreme stellar masses consistent with the JWST observations can be obtained in cosmologies containing axion miniclusters, but the relevant range of axion masses is potentially excluded by superradiance constraints. Explanations relying on isocurvature perturbations from heavy Poisson-distributed PBHs are instead in conflict with existing accretion constraints on PBH abundance. However, such conflicts can be resolved in PBH scenarios with initial spatial clustering.
