OBJECTIVE — Compare GHb among people with diabetes who have and have not received periodontal care.

RESEARCH DESIGN AND METHODS — This cross-sectional study linked 5 years of electronic medical record and dental insurance data for dually insured patients with diabetes, ages 40–70 years (n = 5,103). We assessed the association between annual mean GHb (%) and periodontal care (a proxy for periodontitis) defined using claim codes. Among patients who received periodontal care, we assessed the association between GHb and periodontal treatment intensity. We determined associations using linear regression adjusted for potential confounders and tested for effect modification by age, sex, insulin use, diabetes severity, BMI, and smoking.

RESULTS — Mean GHb was 7.66%; 38% of participants received periodontal care during the 5 years. After multivariate adjustment, patients who received periodontal care had a GHb level 0.08 percentage points higher than patients who did not (P = 0.02). In stratified analyses, the association was present for women (0.18 percentage points higher GHb with periodontal care, \( P < 0.001 \)) but not significant for men (0.008 percentage points lower, \( P = 0.86 \)). In patients who received periodontal care, those with one, and with two or more, surgical treatments had GHb 0.25 (\( P = 0.04 \)) and 0.36 (\( P = 0.002 \)) percentage points lower, respectively, than patients without periodontal surgeries.

CONCLUSIONS — This population-based cross-sectional study showed small associations between periodontal care (a proxy for periodontitis) and higher GHb. Well-controlled longitudinal studies or clinical trials are needed to evaluate causality and temporal trends. Sub-analyses suggest that further investigation of this association among women, and by intensity of periodontal treatment, may be of interest.

RESEARCH DESIGN AND METHODS — Data were extracted from automated dental and medical databases. Instead of the usual 1-year study period, we used 5 years, to ensure adequate time for participants to receive both dental and medical care. Figure 1 shows the inclusion and exclusion criteria. We used four identifiers to link medical and dental data for individuals aged 40–70 years who were continuously insured from 2002 to 2006 by both the Washington Dental Service (a dental insurer) and Group Health Cooperative (an integrated health care system) in Washington state. These procedures are described elsewhere (17).

Diabetes was defined as follows: two fasting glucose levels \( \geq 126 \text{ mg/dl} \), two nonfasting glucose levels \( \geq 200 \text{ mg/dl} \), or one of each within 12 months; GHb \( \geq 7.0\% \); any filled prescription for insulin or oral diabetic agents; or one inpatient or two outpatient diabetes diagnoses. We excluded patients with gestational and secondary diabetes (18). The population with diabetes included both types 1 and type 2 diabetes; but given the age-specific prevalence, most probably have type 2 diabetes (18). Group Health’s institutional review board approved all procedures.

Our exposure variable, periodontal care, was defined by identifying any dental claim submitted with at least one Current Dental Terminology (CDT) periodontal procedure code during the 5-year study period. The CDT codes taken as evidence of periodontal disease included
periodontal maintenance (D4910), gingival (D4240, D4241) and apically (D4245) positioned flaps, osseous surgery (D4260, D4261), bone replacement graft (D4263, D4264), tissue regeneration with biologic materials (D4265), guided tissue regeneration (D4266, D4267), periodontal scaling/root planing (D4342, D4343, D4345), full mouth debridement (D4355), and localized antimicrobial delivery (D4381). Periodontal treatment intensity was defined by two variables: 1) the occurrence and frequency of periodontal surgeries (D4240, D4241, D4245, D4260, D4261, D4263, D4264, D4265, D4266, D4267) (0, 1, ≥2) and 2) an indicator (0/1) of whether the total number of nonsurgical periodontal claims (D4342, D4343, D4335, D4381, D4910) was above the median (7). These exposure variables were assigned once during the 5-year period.

Potential confounders, extracted from the medical databases, included age, sex, and medical insurance type in 2002. Smoking status, routinely collected at medical visits, was defined as nonsmoker if clinical staff recorded patients as non-smokers on 90% or more of their visits during the 5-year period, continuous smokers if >90% of visits were labeled as smoking, and intermittent smokers for the remainder. BMI recorded during clinical visits was calculated using the median of the first three measurements during the 5-year period and categorized (≤24.9, 25–29.9, 30–39.9, and ≥40). To control for potential utilization biases, we included markers of medical care use (number of primary care/urgent visits [square root], number of specialty visits [square root], number of emergency visits [0, 1, ≥2], and the number of GHb tests performed), and surrogate markers of preventive health care–seeking behaviors (number of preventive [well-care] visits [square root] and number of retinal eye exams [square root]). We used RxRisk scores to control for chronic disease morbidity at the beginning of the study (2002) (19). This score is based on an individual’s age, sex, insurance status, and chronic condition profile measured by outpatient pharmacy dispensing. Using pharmacy records, we classified diabetes treatment intensity during the 5-year period as “no diabetes medications,” “oral hypoglycemic only,” and “any use of insulin.” We quantified diabetes severity using the 11-point Diabetes Complication Severity Index (0, 1, 1+) (20).

We used Pearson $\chi^2$ for categorical variables and ANOVA F tests for continuous variables to test differences in percentages and means of population characteristics by periodontal care status. The outcome variable, mean GHb (%), was calculated for each study year. While the distribution of annual mean GHb (%) was right skewed, log transformation yielded similar results, and we elected to use the untransformed mean to ease interpretation. Because an individual can have up to five annual GHb means (2002–2006), we used generalized estimating equations with an independence working correlation structure to account for within-person correlation. Some covariates had extremely high values and were either categorized or square-root transformed to reduce their influence on treatment intensity. The outcome variable, mean GHb (%), was calculated for each study year. While the distribution of annual mean GHb (%) was right skewed, log transformation yielded similar results, and we elected to use the untransformed mean to ease interpretation. RESULTS

findings from a previous study (13). We stratified by age based on diabetes severity (treatment, smoking may obscure the association between periodontitis and glycemic control. We hypothesized that the association between periodontitis and glycemic control. Smoking may obscure the association between periodontitis and glycemic control. We hypothesized that the association between periodontitis and glycemic control. Smoking may obscure the association between periodontitis and glycemic control.

In exploratory multivariate analysis, we tested for interactions separately between periodontal care and each of the following variables: diabetes complication severity, sex, any insulin use (2002–2006), BMI, and smoking status (2002–2006). We tested for effect modification by BMI and smoking based on the hypothesis that inflammation associated with obesity or smoking may obscure the association between periodontitis and glycemic control. We hypothesized that the association between periodontitis and glycemic control may differ by diabetes severity (treatment, complication) because glycemic control in more advanced disease may resist influence. We stratified by age based on findings from a previous study (13).

RESULTS — During the study period (2002–2006), the mean GHb for our dual-insured population with diabetes (n = 5,103) was 7.66%, the average age was 55 years, and 38% received periodontal care (Table 1). Compared with participants without periodontal care, those with periodontal care were younger, used ambulatory services less, and were more likely to smoke, have lower BMI, and be men or be on government-based insurance.

As hypothesized, multivariate analyses linked periodontal care (a proxy for periodontitis) with higher GHb levels. In the unadjusted model, annual mean GHb was 0.11 percentage points higher for people with diabetes who received periodontal care than for those receiving no periodontal care (P = 0.005) (Table 2). The magnitude of the association decreased but remained statistically significant after controlling for age, BMI, and sex (GHb 0.09 percentage points higher; P = 0.02) as well as other variables related to diabetes control, including comorbidity, smoking, medical utilization (primary care visits, specialty care visits, and GHb tests), and number of preventive well-care visits (0.08 percentage points higher; P = 0.04). The association was independent of diabetes severity (0.08 percentage points higher; P = 0.02).

The periodontitis-GHb association was similar within categories of smoking status, BMI, and insulin use. However, the magnitude of the association appeared greater in women than men (interaction term P = 0.002) (Table 3). There was also suggestion that the magnitude of the association may be greater at younger ages (40–49 years old).

Among diabetic patients with periodontal care (n = 1,950), 44% received more than seven nonsurgical periodontal services including periodontal maintenance, local antimicrobials, and other nonsurgical treatments. Surgical care was relatively uncommon; 93% had no periodontal surgeries. 4% had one, and 3% had two or more. As hypothesized, among individuals with periodontal care, those who received greater treatment intensity had lower GHb levels. In the adjusted model, people with more than the median number (7) of nonsurgical visits had GHb 0.13 percentage points lower than individuals with seven or fewer nonsurgical visits (95% CI −0.24 to −0.03; P = 0.01). Compared with people with no periodontal surgeries, those with 1 and 2 or more surgeries had GHb levels that were 0.25 (95% CI −0.49 to −0.01; P = 0.04) and 0.36 (95% CI −0.58 to −0.13; P = 0.002) percentage points lower, respectively. Similar findings were observed in analyses limited to nonsmokers. Among nonsmokers, people with more than the median number (7) of nonsurgical visits had GHb 0.14 percentage points lower than individuals with fewer visits (P = 0.02). Compared with people with no periodontal surgeries, those with one and two or more surgeries had GHb levels that were 0.26 (P = 0.05) and 0.29 (P = 0.006) percentage points lower, respectively.

CONCLUSIONS — In our cross-sectional study of 5,103 patients with diabetes, we observed a small association between higher GHb and receipt of any periodontal care provided by community dentists or periodontists, after accounting for confounders. The association between periodontal care and glycemic control can reflect either periodontitis itself or treatment for the disease. Treatment for periodontitis could worsen certain markers of glycemic control possibly linked to a short-term increase of inflammatory markers (21) or due to the increase in fasting plasma glucose that may happen upon resolution of certain infections. If periodontal care is a marker of periodontitis (which is our primary hypothesis), our results are consistent with a small body of observational evidence linking periodontitis and poor glycemic control in adjusted analyses. A Swedish population-based study of 179 participants with type 2 diabetes reported a 0.6% difference in GHb between patients with and without periodontitis defined by the percentage of teeth with 30% bone loss (9). One multivariate analysis found an association between GHb and probing depth but not attachment loss (11), while another linked GHb to attachment loss but not to probing depth (14). In a cohort study of 88 participants of Pima ancestry with type 2 diabetes, attachment loss was associated with a sixfold increase (95% CI 1.5–25) in the odds of GHb ≥9% after 2 years of follow-up (13).

These smaller studies found stronger associations between periodontitis and GHb than we found between periodontal care and GHb. This difference may relate to our use of periodontal care as a marker of periodontitis. However, we believe this assumption is reasonable for several reasons: 1) all participants were examined by a dentist; 2) in our prior validation analysis, the positive predictive value, sensitivity, and specificity were 84, 80, and 44%, respectively, when the periodontal care code set was compared with chart probing depth of ≥5 mm on two or more teeth in a subset with periodontal charts (22); 3) the proportion of patients receiving periodontal care in our study (38%) resembles the Centers for Disease Control and Prevention (CDC) estimate of 30% of people with diabetes having severe periodontal diseases; (23) and 4) when periodontal codes were categorized by intensity and evaluated in patients who received periodontal care, we saw slightly lower GHb among individuals who received higher treatment intensity. However, we could not identify people with periodontitis who did not receive periodontal care. This misclassification would have biased our results toward the null.
The smaller difference in GHb levels between individuals with and without periodontal care in our study may have been due to our ability to adjust more completely for important confounders. Our analyses adjusted for covariates that captured medical care utilization and preventive health behaviors, variables not included in other studies. However, we could not control for some adjusters used in other studies, including antibiotic use, number of teeth, race, socioeconomic status, and use of nonsteroidal anti-inflammatory medications. Although we could not control for these covariates, our analysis may have partially accounted for them because of the following: our cohort was primarily Caucasian (75%); most, due to local policy, were using statins, which have anti-inflammatory effects; and the population was dual medical/dental insured, which may reduce differences in socioeconomic status. No study, including our own, has controlled for nutritional status beyond BMI. If poor nutrition is associated with both increased periodontal care (as a marker for periodontitis) and increased GHb, our inability to control for potential confounding by nutritional status could bias our results toward finding an association when none exists.

Our stratified analysis suggested that the magnitude of the association between periodontal care and GHb may be greater in younger diabetic subjects (age 40–49).

smaller effect may reflect differences in effectiveness of periodontal treatment delivered in experimental trials compared with periodontal care provided in the community.

Limitations are inherent to our study’s design. As a cross-sectional study, it cannot establish causality or temporality. In addition, since this study is observational, residual confounding may explain the minimal difference in GHb between people with diabetes who did and did not receive periodontal care. However, this study does support using linked populations from medical and dental providers and the associated automated data to expand research on the association between oral health and other medical conditions.

In this study, based on medical care and dental claims data, we found a small positive association between periodontal care (a marker of periodontitis) and higher GHb. In sub-analyses, these findings were stronger among women than men, and we found that among those who were treated for periodontitis, more intense treatment was associated with lower GHb.

Acknowledgments—Washington Dental Service and Group Health Cooperative, employees of five of our coauthors, funded this study. No other potential conflicts of interest relevant to this article were reported.

L.S., R.J.R., R.I., and K.M.N. researched the data; L.S., R.J.R., R.I., K.M.N., P.H., M.C., R.J.G., and W.E.B. contributed to discussion; L.S. wrote manuscript; and L.S., R.J.R., R.I., K.M.N., P.H., M.C., R.J.G., and W.E.B. reviewed/edited the manuscript.

Preliminary findings of this study were presented at the 2009 American Diabetes Association 69th Scientific Sessions.
