Abstract

In this article, we introduce a novel type of spatio-temporal sequential patterns called Constricted Spatio-Temporal Sequential (CSTS) patterns and thoroughly analyze their properties. We demonstrate that the set of CSTS patterns is a concise representation of all spatio-temporal sequential patterns that can be discovered in a given dataset. To measure significance of the discovered CSTS patterns we adapt the participation index measure. We also provide CSTS-Miner: an algorithm that discovers all participation index strong CSTS patterns in event data. We experimentally evaluate the proposed algorithms using two crime-related datasets: Pittsburgh Police Incident Blotter Dataset and Boston Crime Incident Reports Dataset. In the experiments, the CSTS-Miner algorithm is compared with the other four state-of-the-art algorithms: STS-Miner, CSTPM, STBFM and CST-SPMiner. As the results of experiments suggest, the proposed algorithm discovers much fewer patterns than the other selected algorithms. Finally, we provide the examples of interesting crime-related patterns discovered by the proposed CSTS-Miner algorithm.

Keywords: data mining, spatio-temporal sequential patterns, crime-data analysis, patterns discovery, concise representation

1. Introduction

Discovering knowledge in the form of various types of patterns, inference rules or motifs from spatio-temporal events data is a topic attracting increasing attention of researchers world-wide (Han et al., 2011; Zaki et al., 2014). Specifically, many real-world spatio-temporal datasets consist of a set of event types and their event instances defined by geographical locations and time occurrence. An example of a spatio-temporal event dataset is a set of crime event incidents,
such as arson, homicide or vandalism, each of which is assigned an event type, a geographical location and time of occurrence. Discovering sequences of crime types that occur in a spatial area over a time period can contribute to a better understanding of the causes of these crimes and to their elimination (Yu et al., 2016; He & Zheng, 2021).

In order to discover such sequences of spatio-temporal event types, one can consider applying one of the algorithms for spatio-temporal sequential patterns discovery. A spatio-temporal sequential pattern (in brief, ST sequential pattern), introduced in (Huang et al., 2008), is defined as a sequence of event types. By discovering ST sequential patterns, one can obtain insight into spatio-temporal relations between various event types. For example, the discovery of an ST sequential pattern arson $\rightarrow$ vandalism $\rightarrow$ bomb can lead to the critical behavior pattern of a dangerous terrorist.

In the literature, several types of methods and algorithms were already developed for the discovery of ST sequential patterns (see, for example, (Huang et al., 2008; Mohan et al., 2012; Maciąg & Bembenik, 2019; Maciag et al., 2019)). (Huang et al., 2008) introduced the first algorithm called STS-Miner for the discovery of significant ST sequential patterns. (Maciąg & Bembenik, 2019; Maciag et al., 2019) define a significant ST sequential pattern as a pattern, whose participation index measure is greater than the user-specified threshold $\theta$. (Maciag et al., 2019) refers to such a pattern as a PI-strong ST sequential pattern (we adapt this naming convention in this paper).

While the already proposed algorithms (such as STS-Miner (Huang et al., 2008), STBFM (Maciąg & Bembenik, 2019), CST-SP Miner (Maciag et al., 2019), CSTPM (Mohan et al., 2012), STES (Aydin & Angryk, 2016)) can discover PI-strong (closed) ST sequential patterns in some datasets, in practice, the number of discovered redundant patterns can still be too huge to be analyzed by a user of the algorithm. Hence, in this paper, we offer a novel representation of ST sequential patterns which we call Constricted Spatio-Temporal Sequential patterns (in brief, CSTS patterns) and analyze their theoretical properties. As presented in the paper, given the set of CSTS patterns one can approximate participation index values of all ST sequential patterns.

To verify the efficiency and effectiveness of the proposed approach, we use two real-world datasets of crime events: the Pittsburgh Police Incident Blotter Dataset and the Boston Crime Incident Reports Dataset. For example, one of the conducted experiments shows that for the Boston Crime Incidents Reports dataset, the proposed approach is able to discover 65,967 CSTS patterns, while the three algorithms discovering all spatio-temporal sequential patterns provide as many as 228,285 patterns. The discovered 65,967 CSTS patterns can be used to derive all 228,285 spatio-temporal sequential patterns and approximate participation index of each of them with a maximal error of $\pm 0.025$.

1.1. Contributions

The contributions of the paper are as follows:
- We introduce the notion of a **Constricted Spatio-Temporal Sequential (CSTS) pattern** that constitutes concise representation of all ST sequential patterns.

- We thoroughly **analyze theoretical properties of CSTS patterns**. Specifically, we show that the set of CSTS patterns is a subset of the set of closed ST sequential patterns and that each CSTS pattern is also a closed ST sequential pattern. Moreover, we show that given the set of Participation Index (PI)-strong CSTS patterns one can obtain the set of all PI-strong ST sequential patterns and approximate participation index of each of them with an approximation margin of $\pm \varepsilon$.

- We offer a **new algorithm called CSTS-Miner** that discovers PI-strong CSTS patterns. CSTS-Miner applies an **introduced MAX-Tree structure** for more efficient candidate patterns generation. The proposed MAX-Tree is generated in two main phases of CSTS-Miner: the first phase called "top-down", in which all PI-strong ST sequential patterns are generated using the breadth-first strategy, and the second phase called "bottom-up", which calculates PI-strong CSTS patterns. We analyze properties and computation times of CSTS-Miner.

- We experimentally compare the results obtained with the CSTS-Miner algorithm with three other state-of-the-art algorithms discovering ST sequential patterns: the adapted version of STS-Miner (Huang et al., 2008), STBFM (Maciąg & Bembenik, 2019), CSTPM (Mohan et al., 2012), which discover PI-strong ST sequential patterns. Moreover, we also compare CSTS-Miner with the CST-SPMiner algorithm (Maciąg et al., 2019), which discovers PI-strong closed ST sequential patterns. Similarly to CSTS patterns, closed spatio-temporal sequential patterns discovered by CST-SPMiner also constitute a concise representation of all ST sequential patterns. For the purpose of experiments, we selected and preprocessed two crime events datasets: the Pittsburgh Police Incident Blotter Dataset and the Boston Crime Incident Reports Dataset. As we show, CSTS-Miner discovers much fewer redundant patterns than the other selected algorithms. Specifically, as the results of the experiments confirm, CSTS-Miner provides up to 60% fewer patterns compared to the STS-Miner, STBFM and CSTPM algorithms and up to 40% fewer patterns compared to the CST-SPMiner algorithm.

- To the best of our knowledge, for the first time in the literature we provide experimental comparison of the effectiveness and efficiency of the above-mentioned STS-Miner, CSTPM, STBFM and CST-SPMiner algorithms discovering (closed) spatio-temporal sequential patterns. Our implementations (prepared in the C++ language) of the selected algorithms (STS-Miner, STBFM, CSTPM, CST-SPMiner) as well as the proposed
CSTS-Miner algorithm are available at the GitHub repository\footnote{https://github.com/piotrMaciag32/CSTS-Miner}

- Eventually, we provide examples of interesting crime-related patterns discovered by CSTS-Miner from the Pittsburgh Police Incident Blotter Dataset.

1.2. Structure

The structure of the article is as follows. In Section 2, we offer a brief review of the related work. Section 3 offers basic notions of ST sequential patterns. In Section 4, we introduce the notion of a CSTS pattern. In Section 5, we analyze theoretical properties of CSTS patterns. Section 6 describes the proposed CSTS-Miner algorithm. In Section 7, we provide the results of experiments and in Section 8, we conclude the article.

2. Related Work

The discovery of concise representations of various patterns (especially frequent patterns and sequential patterns) attracts researchers’ attention. In (Yan et al., 2003), closed sequential patterns representation was introduced for the first time. Following (Yan et al., 2003), numerous works were dedicated to the problem of more efficient mining of closed sequential patterns. The examples include methods and algorithms offered in (Wang et al., 2007; Wang & Han, 2004) or, more recently, in (Pumarola et al., 2016) and (Gomariz et al., 2013). Other related research directions include discovery of top closed sequential patterns with the highest support (Tzvetkov et al., 2003; Zhang et al., 2015) and parallel discovery of closed sequential patterns (Cong et al., 2005). A survey of the current methods for the discovery of closed sequential patterns can be found in (Fournier-Viger et al., 2017).

While many methods and algorithms were offered to discover various types of spatio-temporal patterns, relatively few of them focused on discovering ST sequential patterns. To this end, in our experiments the proposed CSTS-Miner algorithm is compared with the most representative algorithms mining ST sequential patterns, namely:

- **STS-Miner** (Huang et al., 2008) - the first algorithm offered for the discovery of ST sequential patterns. STS-Miner uses the depth-first strategy. In this work, we adapted STS-Miner to use the participation index measure instead sequence index measure. Thus, the adapted version of STS-Miner is able to discover PI-strong ST sequential patterns.

- **STBFM** (Maciag & Bembenik, 2019) - the algorithm discovering PI-strong ST sequential patterns by means of the breadth-first pattern generation strategy. (Maciag & Bembenik, 2019) introduced a structure called SP-Tree that allows to efficiently generate candidate patterns using their
first and second parent patterns and a children list of the first parent pattern. In addition, [Maciąg & Bembenik, 2019] presented the two variations of STBFM that can discover top-K PI-strong ST sequential patterns. The experiments of [Maciąg & Bembenik, 2019] showed that STBFM is able to discover some interesting crime-related patterns.

- **CST-SPMiner** [Maciag et al., 2019] - the algorithm discovering closed PI-strong ST sequential patterns. CST-SPMiner applies the breadth-first candidate patterns generation strategy to obtain all PI-strong closed ST sequential patterns. For each obtained PI-strong ST sequential pattern \( \vec{s} \), CST-SPMiner determines if this pattern is closed or not using a check condition verifying if \( \vec{s} \) is a closure pattern of both of its parent patterns.

- **CSTPM** [Mohan et al., 2012] - the miner discovering Cascading Spatio-Temporal Patterns (CSTP). CSTP patterns consist of not only ST sequential patterns but also of cascades of event types. In our work, to directly compare CSTPM with the proposed CSTS-Miner, we adapted the CSTPM algorithm for the discovery of ST sequential patterns rather than cascading ST patterns.

The reviews of methods and algorithms for (spatio-temporal) patterns discovery with particular emphasis on spatio-temporal event datasets can be found in [Kisilevich et al., 2010; Li, 2014; Sunitha et al., 2014; Aydin & Angryk, 2016; Maciąg, 2017; Maciąg, 2018; Atluri et al., 2018; Ansari et al., 2019; Aydin et al., 2020].

### 3. Basic Notions

The definitions presented in this section are formulated based on the works [Huang et al., 2008; Maciąg & Bembenik, 2019; Maciag et al., 2019].

Let \( F \) denote a set of \( n \) event types and \( D \) denote a dataset of event instances in which each \( e \in D \) consists of a spatial location, an occurrence time (timestamp) and an event type \( F \in F \). \( D \) will be called a *spatio-temporal event dataset*. Moreover, let \( |D| \) denote the number of event instances in \( D \). The set of all event instances of type \( F \) in dataset \( D \) will be denoted by \( D(F) \).

Let us consider an example of a spatio-temporal event dataset presented in Figure 1. This dataset consists of event instances \( D = \{a_1, a_2, b_1, \ldots, b_8, c_1, \ldots, c_8, d_1, \ldots, d_3, e_1, \ldots, e_5\} \) and a set of five event types \( F = \{A, B, C, D, E\} \).

Spatio-temporal sequential pattern (ST sequential pattern) \( \vec{s} \) is defined as a sequence of elements, each of which is an event type from \( F \) [Huang et al., 2008]. Please note that an event type \( F \in F \) can occur multiple times in an ST pattern.

---

2 Please note that the spatial location of each event instance presented in Figure 1 is specified for simplicity using only one dimension. However, in real datasets, the spatial location of event instances is usually defined by coordinates of two dimensions (for example, in the datasets selected for the experiments, spatial location is defined using longitude and latitude coordinates).
Figure 1: The example of a spatio-temporal event dataset. The figure also presents neighborhood specification of event instances.

sequential pattern $\rightarrow$. Before we provide a formal definition of an ST sequential pattern, we recall the definition of a spatio-temporal neighborhood of an event instance with respect to an event type:

**Definition 1** (Neighborhood of event instance with respect to event type (Huang et al., 2008; Maciag et al., 2019)). For an event instance $e$, the neighborhood of $e$ with respect to an event type $F \in \mathbf{F}$ is denoted by $\mathbf{N}(e, F)$ and is
defined as follows:

$$N(e, F) = \{ p \mid p \in D(F) \land \text{distance}(p.\text{location}, e.\text{location}) \leq R \land (p.\text{time} - e.\text{time}) \in (0, T]\},$$

where $R$ and $T$ are user-given spatial distance and time window thresholds, respectively.

In Figure 1, the neighborhood $N(a_1, B)$ consists of event instances $\{b_1, b_2\}$. Similarly, the neighborhood $N(c_1, E) = \{e_1, e_2\}$. The spatial distance threshold of neighborhoods given in Figure 1 is $R = 10$, while the time window threshold is equal to $T = 20$. In our experiments, the spatial distance between locations of two event instances is calculated as the Euclidean distance between these locations. Please note that according to Definition 1, an event instance $e_j$ can be located in a neighborhood of an event instance $e_i$ only if the occurrence time of $e_j$ is greater than the occurrence time of $e_i$ (i.e., the two event instances with the same occurrence time can not mutually belong to their neighborhoods because the difference between their occurrence time would be $e_i.\text{time} - e_j.\text{time} = 0$).

**Definition 2** (Spatio-temporal sequential pattern). A spatio-temporal sequential pattern (in brief, ST sequential pattern) is a sequence of event types in $F$. The number of elements of the sequence is called its length. $i$-th element of sequence $\vec{s}$ is denoted by $\vec{s}[i]$. Sequence $\vec{s}$, which consists of $m$ elements is denoted as $\vec{s}[1] \rightarrow \vec{s}[2] \rightarrow \cdots \rightarrow \vec{s}[m]$. The number of elements of sequence $\vec{s}$ is defined as its length.

The example of an ST sequential pattern for the dataset presented in Figure 1 is $\vec{s} = A \rightarrow B \rightarrow C$, the length of which is 3. The important question is how to efficiently calculate neighborhoods of event instances? In our implementation, we adapted the plane sweep algorithm (see e.g. (Arge et al., 1998)) that has computational complexity of $O(|D(F)| \cdot \log(|D(F)|))$.

**Definition 3** (Set of event instances supporting an element of an ST sequential pattern (Huang et al., 2008; Maciag et al., 2019)). A Set of event instances supporting $i$-th element of ST sequential pattern $\vec{s}$ is denoted by $I(\vec{s}, i)$ and is defined as follows:

$$I(\vec{s}, i) = \begin{cases} D(\vec{s}[1]) & \text{when } i = 1, \\ \bigcup_{e \in I(\vec{s}, i-1)} N(e, \vec{s}[i]) & \text{when } i > 1. \end{cases}$$

For each ST sequential pattern $\vec{s}$, we can unambiguously distinguish sets of event instances supporting elements of that pattern. For the first element of a pattern, the set of event instances $I(\vec{s}, 1)$ supporting that element is defined simply as all event instances of event type $\vec{s}[1]$ in $D$. For every next element of $\vec{s}$ (say $i$), the set of supporting event instances $I(\vec{s}, i)$ consists of all those
event instances of event type $\overrightarrow{s}[i]$, which belong to neighborhoods of instances contained in the supporting set $I(\overrightarrow{s}, i - 1)$.

Let us consider an example of a previously given ST sequential pattern $\overrightarrow{s} = A \rightarrow B \rightarrow C$ of the dataset in Figure 1. The sets of event instances supporting $\overrightarrow{s}$ are as follows:

- $I(\overrightarrow{s}, 1) = D(A) = \{a_1, a_2\}$;
- $I(\overrightarrow{s}, 2) = \bigcup_{a \in I(\overrightarrow{s}, 1)} N(a, B) = \{b_1, b_2, b_3, b_4\}$;
- $I(\overrightarrow{s}, 3) = \bigcup_{b \in I(\overrightarrow{s}, 2)} N(b, C) = \{c_1, c_2, c_3\}$;

In this article, we apply the previously introduced in (Mohan et al., 2012; Aydin & Angryk, 2016; Maciąg & Bembenik, 2019) participation ratio and participation index measures of significance of discovered patterns. The participation ratio of an $i$-th element of an ST sequential pattern $\overrightarrow{s}$ expresses the quotient of the number of event instances supporting $i$-th element of $\overrightarrow{s}$ to the number of event instances of $\overrightarrow{s}[i]$ event type in $D$.

**Definition 4** (Participation ratio (Maciąg et al., 2019)). The participation ratio of an $i$-th element of ST sequential pattern $\overrightarrow{s}$, where $i \geq 1$, is denoted by $PR(\overrightarrow{s}, i)$ and is defined as the ratio of the cardinality of the set of event instances supporting $i$-th element of $\overrightarrow{s}$ to the number of all instances of type $\overrightarrow{s}[i]$ in the dataset $D$; that is: $PR(\overrightarrow{s}, i) = \frac{|I(\overrightarrow{s}, i)|}{|D(\overrightarrow{s}[i])|}$.

By Definition 4, the value of participation ratio is always in the range [0,1]. Participation index is defined as the minimal of participation ratios of all elements of an ST sequential pattern.

**Definition 5** (Participation index (Maciąg et al., 2019)). The participation index of ST sequential pattern $\overrightarrow{s} = \overrightarrow{s}[1] \rightarrow \overrightarrow{s}[2] \rightarrow \cdots \rightarrow \overrightarrow{s}[m]$ is denoted by $PI(\overrightarrow{s})$ and is defined as the minimum from the participation ratios of all elements of $\overrightarrow{s}$; that is, $PI(\overrightarrow{s}) = \min\{PR(\overrightarrow{s}, i) | i = 1, 2, \ldots, m\}$.

In Table 1, we listed all ST sequential patterns for which participation indexes are greater than 0 for the dataset of Figure 1.

**Definition 6** (PI-strong ST sequential pattern). A candidate ST sequential pattern $\overrightarrow{s}$ is called PI-strong if its participation index $PI(\overrightarrow{s})$ is greater than the participation index threshold $\theta$.

Discovery of all PI-strong ST sequential patterns can be performed, for example, using the STBFM algorithm introduced in (Maciąg & Bembenik, 2019).

**Definition 7** (Proper Subsequence and proper supersequence of an ST sequential pattern). Let $\overrightarrow{s_1} = \overrightarrow{s_1}[1] \rightarrow \overrightarrow{s_1}[2] \rightarrow \cdots \rightarrow \overrightarrow{s_1}[m_1]$ and $\overrightarrow{s_2} = \overrightarrow{s_2}[1] \rightarrow \overrightarrow{s_2}[2] \rightarrow \cdots \overrightarrow{s_2}[m_2]$ be ST sequential patterns. $\overrightarrow{s_1}$ is a subsequence of $\overrightarrow{s_2}$ and
Table 1: All ST sequential patterns and their participation indexes (provided in parentheses next to the patterns) for the dataset of Figure 1.

| Pattern length | Patterns set |
|----------------|-------------|
| \( L_1(F) \)  | \( A(1), B(1), C(1), D(1), E(1) \) |
| \( L_2 \)     | \( A \rightarrow B(0.5), \ B \rightarrow B(0.625), \ B \rightarrow C(0.5), \ B \rightarrow D(1), \ C \rightarrow E(0.8), \ E \rightarrow C(0.5) \) |
| \( L_3 \)     | \( A \rightarrow B \rightarrow B(0.25), \ A \rightarrow B \rightarrow C(0.375), \ A \rightarrow B \rightarrow D(0.5), \ B \rightarrow B \rightarrow C(0.5), \ B \rightarrow B \rightarrow D(0.33), \ B \rightarrow C \rightarrow E(0.375), \ C \rightarrow E \rightarrow C(0.25) \) |
| \( L_4 \)     | \( A \rightarrow B \rightarrow B \rightarrow C \rightarrow E(0.25), \ A \rightarrow B \rightarrow C \rightarrow E(0.375), \ B \rightarrow B \rightarrow C \rightarrow E(0.375), \ B \rightarrow C \rightarrow E \rightarrow C(0.25) \) |
| \( L_5 \)     | \( A \rightarrow B \rightarrow B \rightarrow C \rightarrow E(0.25), \ A \rightarrow B \rightarrow C \rightarrow E(0.25) \) |
| \( L_6 \)     | \( A \rightarrow B \rightarrow B \rightarrow C \rightarrow E \rightarrow C(0.25) \) |

\( \vec{s}_2 \) is a supersequence of \( \vec{s}_1 \) if \( m_1 \leq m_2 \) and there exits an integer \( k \), where \( 0 \leq k \leq m_2 - m_1 \), such that \( \vec{s}_1[1] = \vec{s}_2[1+k] \wedge \vec{s}_1[2] = \vec{s}_2[2+k] \wedge \cdots \wedge \vec{s}_1[m_1] = \vec{s}_2[m_1+k] \).

If \( m_1 < m_2 \), then \( \vec{s}_1 \) is a proper subsequence of \( \vec{s}_2 \) and \( \vec{s}_2 \) is a proper supersequence of \( \vec{s}_1 \).

**Theorem 1** (Anti-monotonicity property of the participation index for supersequences (Maciag et al., 2019)). Let \( \vec{s}_1 \) and \( \vec{s}_2 \) be ST sequential patterns. If \( \vec{s}_1 \) is a subsequence of \( \vec{s}_2 \), then \( PI(\vec{s}_1) \geq PI(\vec{s}_2) \).

For the dataset presented in Figure 1, \( \vec{s}_1 = A \rightarrow B \) is a proper subsequence of \( \vec{s}_2 = A \rightarrow B \rightarrow C \rightarrow E \) (\( \vec{s}_2 \) is a proper supersequence of \( \vec{s}_1 \)). As follows from Theorem 1, the \( PI \) value of an ST sequential pattern \( \vec{s}_2 \) is always less than or equal to the \( PI \) value of its proper subsequence \( \vec{s}_1 \). The STBFM, CST-SPMiner and CSTPM algorithms apply Theorem 1 to efficiently generate candidate ST sequential patterns using the breadth-first search strategy.

(Maciag et al., 2019) introduced a concise and lossless representation of ST sequential patterns called closed ST sequential patterns. The important property of closed ST sequential patterns is that one can obtain the value of participation index of any ST sequential pattern given only the set of all closed ST sequential patterns. In the following section of this work, we theoretically and experimentally compare the proposed constricted ST sequential patterns.

---

3We refer the reader to (Maciag et al., 2019) for the proof of the theorem.
to the closed ST sequential patterns. Thus, Definition 8 recalls the notions of closed ST sequential pattern, closure of an ST sequential pattern and PI-strong closed ST sequential pattern.

**Definition 8** (Closed ST sequential pattern and closure of an ST sequential pattern (Maciag et al., 2019)). ST sequential pattern $\mathbf{s}_1$ is closed if there exists no proper supersequence $\mathbf{s}_2$ of $\mathbf{s}_1$, such that the participation index $PI(\mathbf{s}_2) = PI(\mathbf{s}_1)$.

A closure of ST sequential pattern $\mathbf{s}_1$ is a supersequence $\mathbf{s}_2$ of $\mathbf{s}_1$, such that $\mathbf{s}_2$ is a closed ST sequential pattern and $PI(\mathbf{s}_2) = PI(\mathbf{s}_1)$.

**Definition 9.** A PI-strong closed ST sequential pattern is a closed ST sequential pattern whose participation index is greater than the threshold $\theta$.

For example, for the set of ST sequential patterns of Table 1, $A \rightarrow B \rightarrow B \rightarrow C \rightarrow E \rightarrow C(0.25)$ is a closed ST sequential pattern. $A \rightarrow B \rightarrow B \rightarrow C \rightarrow E \rightarrow C(0.25)$ is also a closure of the following patterns:

- $A \rightarrow B \rightarrow B(0.25)$,
- $C \rightarrow E \rightarrow C(0.25)$,
- $A \rightarrow B \rightarrow B \rightarrow C(0.25)$,
- $B \rightarrow C \rightarrow E \rightarrow C(0.25)$,
- $A \rightarrow B \rightarrow B \rightarrow C \rightarrow E(0.25)$,
- $A \rightarrow B \rightarrow C \rightarrow E \rightarrow C(0.25)$,
- $B \rightarrow B \rightarrow C \rightarrow E \rightarrow C(0.25)$.

An ST sequential pattern can be closed and be its own closure. For example, $B \rightarrow B(0.625)$ is a closed ST sequential pattern and it is also its own closure. Please note that according to Definition 8 an ST sequential pattern can have more than one closure. For example, pattern $B \rightarrow C \rightarrow E(0.375)$ has two closures:

- $A \rightarrow B \rightarrow C \rightarrow E(0.375)$,
- $B \rightarrow B \rightarrow C \rightarrow E(0.375)$.

4. Discovery of Constricted ST Sequential Patterns

In this section, we first present our motivation for introducing Constricted ST Sequential patterns. Next, we provide the elementary notions of such type of patterns.
4.1. Motivation

Closed ST sequential patterns of Definition 8 are a concise representation of all ST sequential patterns (the set of closed ST sequential patterns can be used to derive all ST sequential patterns). However, in the case of real-world spatio-temporal event data, participation indexes of ST sequential patterns strictly depend on the specification of the neighbourhoods of event instances as well as spatial and temporal distribution of the locations of event instances in the dataset $D$. Specifically, for a given ST sequential pattern $\vec{s}$ of length $k$, its proper supersequence patterns of length greater than $k$ usually have only slightly smaller values of participation indexes than $\vec{s}$. According to Definition 8, none of such supersequences can constitute a closure pattern of $\vec{s}$ and thus be a closed ST sequential pattern. Nevertheless, providing only supersequence patterns of $\vec{s}$ often will allow us to approximate the participation index of $\vec{s}$.

Hence, in this paper, we offer a notion of a constricted ST sequential pattern. We define a constricted ST sequential pattern $\vec{s}_1$ as such maximal (that is the longest) supersequence of pattern $\vec{s}$ for which (i) the difference between participation indexes of $\vec{s}$ and $\vec{s}_1$ is minimal and (ii) participation index of $\vec{s}_1$ is greater than or equal to the participation index of $\vec{s}$ minus approximation margin $\varepsilon$. We show in Section 5 that given the set of PI-strong constricted ST sequential patterns, one can obtain the set of all PI-strong ST sequential patterns and approximate participation indexes of each of them with an approximation margin $\pm \varepsilon$.

4.2. Elementary Notions

Let us begin with the definitions of a maximal supersequence of an ST sequential pattern and a minimal proper supersequence of an ST sequential pattern.

Definition 10 (Maximal supersequence of an ST sequential pattern). For an ST sequential pattern $\vec{s}_1$ of a dataset $D$, its maximal ST supersequence pattern $\vec{s}_2$ is such a supersequence of $\vec{s}_1$ whose length is the greatest. Please note that $\vec{s}_1$ can have more than one maximal ST supersequence pattern.

Definition 11 (Minimal proper supersequence of an ST sequential pattern). For an ST sequential pattern $\vec{s}_1$ of a dataset $D$, its minimal proper supersequence pattern $\vec{s}_2$ is such a proper supersequence of $\vec{s}_1$ whose length is the smallest. Please note that $\vec{s}_1$ can have more than one minimal proper ST supersequence patterns.

The set of supersequences of the pattern $\vec{s}_1 = B \rightarrow B$ presented in Table 1 is:

- $B \rightarrow B$,
From which, the maximal supersequence of the pattern $\overrightarrow{s_1}$ is $A \rightarrow B \rightarrow B \rightarrow C \rightarrow E \rightarrow C$ and the minimal proper supersequences of $\overrightarrow{s_1}$ are $A \rightarrow B \rightarrow B$, $B \rightarrow B \rightarrow C$, $B \rightarrow B \rightarrow C \rightarrow E$.

**Definition 12** ($\varepsilon$-constricted maximal supersequence of an ST sequential pattern). $\varepsilon$-constricted maximal supersequence $\overrightarrow{s_1}$ of an ST sequential pattern $\overrightarrow{s}$ (in brief, Constricted ST Sequential pattern, CSTS pattern) is such a supersequence of $\overrightarrow{s}$ which preserves the two conditions:

1. $PI(\overrightarrow{s_1}) \geq PI(\overrightarrow{s}) - \varepsilon$, and

2. the difference $PI(\overrightarrow{s}) - PI(\overrightarrow{s_1})$ is minimal over the set of all maximal supersequences of $\overrightarrow{s_1}$.

We denote the set of all $\varepsilon$-constricted maximal supersequences of pattern $\overrightarrow{s}$ as $C_{max}(\overrightarrow{s})$, $\varepsilon$ is an approximation margin parameter, whose value is user-specified and is in the range $[0,1]$.

To illustrate Definition 12 let us consider again the pattern $\overrightarrow{s} = B \rightarrow B$ presented in Table 1 and let us assume that $\varepsilon = 0.25$. The participation index of $\overrightarrow{s}$ equals 0.675. The $\varepsilon$-constricted supersequence of $\overrightarrow{s}$ is the ST sequential pattern $C_{max}(\overrightarrow{s}) = \{B \rightarrow B \rightarrow C \rightarrow E\}$, whose participation index equals 0.325.

Please note that an ST sequential pattern can have more than one $\varepsilon$-constricted maximal supersequence. For example, let us consider ST sequential pattern $\overrightarrow{s} = B \rightarrow C \rightarrow E$ presented in Table 1 and let us assume that approximation margin $\varepsilon = 0.1$. The two $\varepsilon$-constricted maximal supersequences of $\overrightarrow{s}$ are: $C_{max}(\overrightarrow{s}) = \{A \rightarrow B \rightarrow C \rightarrow E, B \rightarrow C \rightarrow E\}$, whose $PI$ values are both equal to 0.375. Please also note that according to Definition 12 an ST sequential pattern $\overrightarrow{s}$ can be its own $\varepsilon$-constricted maximal supersequence.

From Definition 12 follows that an ST sequential pattern $\overrightarrow{s}$ can be a CSTS pattern of the other ST sequential pattern, but also can have its own CSTS pattern.
pattern. For example, let us consider the pattern $\mathcal{s} = B \rightarrow B \rightarrow C \rightarrow E$ from Table 1 and assume that $\varepsilon = 0.25$. $\mathcal{s}$ is a CSTS pattern of the ST sequential pattern $B \rightarrow B$, but also has its own CSTS pattern $C^{\text{max}}(\mathcal{s}) = \{A \rightarrow B \rightarrow B \rightarrow C \rightarrow E \rightarrow C\}$.

**Definition 13.** By $\mathcal{RC}^{\text{max}}(\mathcal{s}_1)$ (reverse maximal closure set) we denote a set of ST sequential patterns for which $\mathcal{s}_1$ is the $\varepsilon$-constricted maximal supersequence ($\mathcal{s}_1$ is a CSTS pattern).

Let us consider an ST sequential pattern $\mathcal{s}_1 = A \rightarrow B \rightarrow B \rightarrow C \rightarrow E \rightarrow C$ from Table 1 whose $PI = 0.25$. Additionally, let us assume that approximation margin is $\varepsilon = 0.25$. The set $\mathcal{RC}^{\text{max}}(\mathcal{s}_1)$ is (the numbers in parentheses specify participation indexes):

- $A \rightarrow B \rightarrow B \rightarrow C \rightarrow E \rightarrow C(0.25)$,
- $A \rightarrow B \rightarrow B \rightarrow C \rightarrow E(0.25)$,
- $B \rightarrow B \rightarrow C \rightarrow E \rightarrow C(0.25)$,
- $A \rightarrow B \rightarrow B \rightarrow C \rightarrow E(0.25)$,
- $B \rightarrow B \rightarrow C \rightarrow E(0.375)$,
- $B \rightarrow C \rightarrow E \rightarrow C(0.25)$,
- $A \rightarrow B \rightarrow B(0.25)$,
- $B \rightarrow B \rightarrow C(0.5)$,
- $B \rightarrow C \rightarrow E(0.375)$,
- $A \rightarrow B(0.5), B \rightarrow C(0.5), E \rightarrow C(0.5)$.

The set $\mathcal{RC}^{\text{max}}(\mathcal{s}_1)$ is applied by the proposed CSTS-Miner algorithm to identify CSTS patterns.

**Definition 14 (The set of all PI-strong CSTS patterns).** The set of all PI-strong CSTS patterns is defined as the set of all ST sequential patterns that are PI-strong (according to Definition 6) and are CSTS patterns (according to Definition 12).

The proposed CSTS-Miner algorithm first discovers all PI-strong ST sequential patterns and then subsequently returns only those of them which are PI-strong CSTS patterns.
5. Theoretical Properties of $\varepsilon$-constricted Maximal ST Sequential Patterns

In this section, we derive theoretical properties of the introduced notions of (PI-strong) CSTS patterns. Specifically, we show that:

• for the parameter $\varepsilon = 0$ the set of all CSTS patterns is equivalent to the set of all closed ST sequential patterns (Lemma 1);

• each CSTS pattern is a closed ST sequential pattern regardless of the value of the approximation margin $\varepsilon$ (Lemma 2);

• the set of CSTS patterns is a subset of the set of closed ST patterns for any value of the approximation margin parameter $\varepsilon$ (Theorem 2);

• it can be verified if an ST sequential pattern $\mathbf{s} \rightarrow$ is PI-strong given the set of PI-strong CSTS patterns and how to approximate $PI$ value of $\mathbf{s} \rightarrow$ (Lemma 3);

• one can approximate the value of $PI$ of $\mathbf{s} \rightarrow$ with an error no greater than $\pm \varepsilon$ (Lemma 4).

Lemma 1 shows that given an ST sequential pattern $\mathbf{s} \rightarrow$ and its CSTS pattern $\mathbf{s} \rightarrow_1$ as well as for $\varepsilon = 0$, $\mathbf{s} \rightarrow_1$ is a closure of $\mathbf{s} \rightarrow$ and $\mathbf{s} \rightarrow_1$ is a closed ST sequential pattern.

**Lemma 1.** Let $\mathbf{s} \rightarrow$ be an ST sequential pattern, $\varepsilon = 0$ and $\mathbf{s} \rightarrow_1$ be a CSTS pattern of $\mathbf{s} \rightarrow$. The CSTS pattern $\mathbf{s} \rightarrow_1$ is a closure of $\mathbf{s} \rightarrow$ and $\mathbf{s} \rightarrow_1$ is a closed ST sequential pattern.

**Proof.** The proof of lemma follows from Definitions 8 and 12. By Definition 8 a closure of ST sequential pattern $\mathbf{s} \rightarrow$ is such a closed ST sequential pattern $\mathbf{s} \rightarrow^*$ that is a supersequence of $\mathbf{s} \rightarrow$ and whose $PI(\mathbf{s} \rightarrow^*) = PI(\mathbf{s} \rightarrow)$. For $\varepsilon = 0$ we have:

- the $PI$ value of $\mathbf{s} \rightarrow_1$ being a CSTS pattern of $\mathbf{s} \rightarrow$ equals $PI$ value of $\mathbf{s} \rightarrow$,
- CSTS pattern $\mathbf{s} \rightarrow_1$ is a maximal supersequence of $\mathbf{s} \rightarrow$.

Thus, for $\varepsilon = 0$ the CSTS pattern $\mathbf{s} \rightarrow_1$ is a closed ST sequential pattern. $\square$

It follows from Lemma 1 that for the parameter $\varepsilon = 0$ the set of all PI-strong CSTS patterns is equivalent to the set of all PI-strong closed ST sequential patterns (in other words, for $\varepsilon = 0$ the proposed algorithm CSTS-Miner will return the same patterns set as the CST-SPMiner of (Maciag et al., 2019)).

In fact, in Lemma 2 we show that each CSTS pattern is a closed ST sequential pattern regardless of the value of the approximation margin $\varepsilon$.

**Lemma 2.** Each CSTS pattern is a closed ST sequential pattern regardless of the value of approximation margin $\varepsilon$. 

14
Proof. Let us assume that $\vec{s}_1$ is a CSTS pattern of an ST sequential pattern $\vec{s}$ given any value of $\varepsilon$. Now, let us assume that there exists a proper maximal supersequence $\vec{s}_2$ of $\vec{s}_1$ whose participation index $PI(\vec{s}_2)$ equals the participation index $PI(\vec{s}_1)$, that is $\vec{s}_2$ is a closure of $\vec{s}_1$. By Definition 8 $\vec{s}_2$ has to be a closed ST sequential pattern. However, as follows from Definition 12 this would contradict that $\vec{s}_1$ is a CSTS pattern. Hence, CSTS pattern $\vec{s}_1$ is a closed ST sequential pattern.

In Theorem 2 we show that the set of CSTS patterns is a subset of the set of closed ST patterns for any value of the approximation margin parameter $\varepsilon$.

**Theorem 2.** For any $\varepsilon \in [0,1]$, the set of all CSTS patterns is a subset of the set of all closed ST sequential patterns.

**Proof.** We already showed in Lemma 1 that for $\varepsilon = 0$, the set of all CSTS patterns is equal to the set of all closed ST sequential patterns. We also presented in Lemma 2 that each CSTS pattern is a closed ST sequential pattern regardless of $\varepsilon$ value. Let us assume that $\varepsilon > 0$. If there exists a closed ST sequential pattern $\vec{s}$ that has a CSTS pattern and $\vec{s}$ is not a CSTS pattern itself, then $\vec{s}$ will not be included in the set of CSTS patterns (in such a case, the CSTS patterns set is a proper subset of the set of closed ST sequential patterns). Otherwise, if each closed ST sequential pattern is also a CSTS pattern, then the set of CSTS patterns is equal to the set of all closed ST sequential patterns. In any case, the CSTS patterns set is a subset of the closed ST sequential patterns set.

Theorem 2 shows that the number of the discovered CSTS patterns is less than or equal to the number of closed ST sequential patterns. Thus, by discovering of only CSTS patterns one can always obtain as many as all closed ST sequential patterns.

Lemma 3 shows how to verify if an ST sequential pattern $\vec{s}$ is PI-strong given the set of PI-strong CSTS patterns and how to approximate its $PI$ value.

**Lemma 3.** For each ST sequential pattern holds:

(i). An ST sequential pattern $\vec{s}$ is PI-strong only if there exists a supersequence of $\vec{s}$ in the set of PI-strong CSTS patterns.

(ii). The participation index value of a PI-strong ST sequential pattern $\vec{s}$ is equal to or less than $PI(\vec{s}_1) + \varepsilon$, where $\vec{s}_1$ is such a minimal proper supersequence of $\vec{s}$ in PI-strong CSTS patterns, whose $PI(\vec{s}_1)$ is the greatest.

**Proof.**

Ad (i). Follows immediately from Theorem 1.

Ad (ii). Case 1. Let us first assume that there is only one supersequence $\vec{s}_1$ of $\vec{s}$ in the set of PI-strong CSTS patterns. In this case, $\vec{s}_1$ is a $\varepsilon$-constricted maximal ST supersequence of $\vec{s}$ and by Definition 12 $PI(\vec{s}) \in [PI(\vec{s}_1), PI(\vec{s}_1) + \varepsilon]$. 

15
Case 2. Now let us assume that there is more than one proper supersequence of $\overrightarrow{s}$ in the set of PI-strong CSTS patterns. Since we can not indicate which one of them is $\varepsilon$-constricted maximal ST supersequence, then $PI(\overrightarrow{s}) \in [PI(\overrightarrow{s}_1), PI(\overrightarrow{s}_1) + \varepsilon]$, where $\overrightarrow{s}_1$ is a minimal proper supersequence from all proper supersequences of $\overrightarrow{s}$ in PI-strong CSTS patterns.

Lemma 3 indicates that the set of PI-strong CSTS patterns (unlike the set of all PI-strong closed ST sequential patterns) is not a lossless representation of all PI-strong ST sequential patterns in a sense that the PI value of a PI-strong ST sequential pattern can be obtained from the set of PI-strong CSTS patterns only with a certain approximation. The question is how much the approximation of such PI value of a PI-strong ST sequential pattern differs from its exact PI value. In Lemma 4 we provide the value of such maximal approximation.

**Lemma 4.** Given an ST sequential pattern $\overrightarrow{s}$ that has a supersequence in the CSTS patterns set one can not:

- underestimate the exact PI value of $\overrightarrow{s}$ by less than $PI(\overrightarrow{s}) - \varepsilon$, and
- overestimate the exact PI value of $\overrightarrow{s}$ by more than $PI(\overrightarrow{s}) + \varepsilon$.

**Proof.** Let us assume that $\overrightarrow{s}_1$ is any proper supersequence of $\overrightarrow{s}$ in the set of CSTS patterns. We will consider the two extreme cases:

**Case 1.** The value of $PI(\overrightarrow{s}_1)$ equals $PI(\overrightarrow{s}) - \varepsilon$. In such a case, one can not underestimate $PI(\overrightarrow{s})$ by less than $PI(\overrightarrow{s}) - \varepsilon$.

**Case 2.** The value of $PI(\overrightarrow{s}_1)$ equals $PI(\overrightarrow{s})$. In such a case, one can not overestimate $PI(\overrightarrow{s})$ by more than $PI(\overrightarrow{s}) + \varepsilon$.

Thus, the estimation of the $PI(\overrightarrow{s})$ value of the pattern $\overrightarrow{s}$ given the set of CSTS patterns is always in the range $[PI(\overrightarrow{s}) - \varepsilon, PI(\overrightarrow{s}) + \varepsilon]$.

6. The Constricted ST Sequential Patterns Miner

This section introduces our algorithm called CSTS-Miner for discovering the set of all PI-strong CSTS patterns. In Table 2 we present the notation used in the algorithms of this section. CSTS-Miner is presented in Algorithm 1. The algorithm consists of two phases: i. "top-down" - iterative generation of all PI-strong ST sequential patterns of length $k$ from patterns of length $k - 1$ until it is impossible to generate new patterns; ii. "bottom-up" - calculation of PI-strong CSTS patterns. The "top-down" phase adapts the previously introduced STBFM algorithm for the discovery of PI-strong ST sequential patterns. Specifically, to efficiently generate new PI-strong patterns of length $k$ from PI-strong patterns of length $k - 1$, we adapted the SP-tree structure and extended it to the proposed MAX-Tree structure. MAX-Tree is used to not only iteratively
generate new patterns but also, unlike SP-Tree offered in [Maciąg & Bembenik, 2019], to identify all PI-strong CSTS patterns. The "bottom-up" phase calculates PI-strong CSTS patterns in a recursive way starting with the set of the longest PI-strong ST sequential patterns \(L_k\) obtained in the "top-down" phase.

| Notation | Description |
|----------|-------------|
| \(D\)    | A dataset of spatio-temporal event instances |
| \(F\)    | A set of event types |
| \(\vec{s}\)  | An ST sequential pattern |
| \(N(e, F)\) | Neighborhood of event instance \(e\) with respect to event type \(F \in F\) |
| \(I(\vec{s}, i)\) | A set of event instances supporting \(i\)-th element of \(\vec{s}\) |
| \(PR(\vec{s}, i)\) | Participation ratio of \(i\)-th element of \(\vec{s}\) |
| \(PI(\vec{s})\) | Participation index of pattern \(\vec{s}\) |
| \(\text{children}(\vec{s}), \vec{s} \cdot \text{children}\) | Children patterns of \(\vec{s}\) |
| \(\text{parent}_1(\vec{s}), \vec{s} \cdot \text{parent}_1\) | First parent of pattern \(\vec{s}\) |
| \(\text{parent}_2(\vec{s}), \vec{s} \cdot \text{parent}_2\) | Second parent of pattern \(\vec{s}\) |
| \(C^{\text{max}}(\vec{s}), \vec{s} \cdot C^{\text{max}}\) | A set of \(\varepsilon\)-constricted maximal supersequences of \(\vec{s}\) |
| \(\mathcal{R}C(\vec{s}), \vec{s} \cdot \mathcal{R}C\) | Set of ST sequential patterns, for which \(\vec{s}\) is a \(\varepsilon\)-constricted maximal supersequence |
| \(\theta\) | Participation index threshold of discovered patterns |
| \(\varepsilon\) | Approximation margin |

### 6.1. The "Top-down" Phase of the CSTS-Miner Algorithm

The "top-down" phase of Algorithm 1 is conducted by executing steps 1 to 18 of this algorithm. In step 1 of Algorithm 1, a singular candidate ST sequential pattern is generated from each event type in \(F\) and remembered in the set \(L_1\) (patterns in \(L_1\) constitute the first level of MAX-Tree). By Definitions 4 and 5, singular patterns are always PI-strong since their PI values are equal to 1.

Subsequently, the PI-strong ST sequential patterns of length 2 are generated and remembered as \(L_2\). The generation of such PI-strong ST sequential patterns is conducted in steps 3 to 13 using two nested loops, each of which iterates over all patterns in \(L_1\). A new candidate pattern \(\vec{s}\) of length 2 is always generated by concatenating the two event types of singular patterns \(\vec{s}_i\) and \(\vec{s}_j\). We will refer to the patterns \(\vec{s}_i\) and \(\vec{s}_j\) as the first and the second parent of \(\vec{s}\), respectively. Please note that \(\vec{s}\) can consist of two the same event types (in such a case, \(\vec{s}_i = \vec{s}_j\)). The set of instances supporting the second element of \(\vec{s}\) is calculated in step 6 and consists of event instances of type \(\vec{s}[2]\) in \(D\) which belong to neighborhoods of event instances in the set \(I(\vec{s}_j, 1)\).
The participation index of the candidate generated pattern $\overrightarrow{s}$ is calculated and verified in steps 7 and 8 of Algorithm 1. If $\overrightarrow{s}$ occurred to be PI-strong, then $\overrightarrow{s}$ is inserted into the list of children of its first parent children ($\overrightarrow{s}_1$) and into the set $L_2$.

**Algorithm 1 CSTS-Miner($D, F, R, T, \theta, \varepsilon$)**

**Input:** $D$ - spatio-temporal event dataset, $F$ - set of event types, $R$ - spatial threshold value, $T$ - time window threshold value, $\theta$ - participation index threshold value, $\varepsilon$ - approximation margin.

**Assumption:** $L_k$ - a set of PI-strong ST sequential patterns of length $k$.

**Output:** $\bigcup_k \{ \overrightarrow{s} \in L_k | \overrightarrow{s}.RC \neq \emptyset \lor (\overrightarrow{s}.RC = \emptyset \land \overrightarrow{s}.Cmax = \emptyset) \}$ - a set of PI-strong CSTS patterns.

1. $L_1 :=$ generate patterns of length 1 from all event types in $F$
2. $L_2 := \emptyset$
3. for each $\overrightarrow{s}_i \in L_1$
4.  for each $\overrightarrow{s}_j \in L_1$
5.  $\overrightarrow{s} := \overrightarrow{s}_i[1] \rightarrow \overrightarrow{s}_j[1]$
6.  $\text{I}(\overrightarrow{s}, 2) := \bigcup_{e \in \text{I}(\overrightarrow{s}_i, 1)} N_{\overrightarrow{s}[2]}(e)$
7.  $\overrightarrow{s}.PI := PR(\overrightarrow{s}, 2)$
8.  if $\overrightarrow{s}.PI > \theta$ then
9.     $\overrightarrow{s}.parent_1 := \overrightarrow{s}_i; \overrightarrow{s}.parent_2 := \overrightarrow{s}_j$
10.     Add $\overrightarrow{s}$ to $\overrightarrow{s}.parent_1$.children; add $\overrightarrow{s}$ to $L_2$
11. end if
12. end for
13. end for
14. $k := 2$
15. while $L_k \neq \emptyset$
16.  $k := k + 1$
17.  $L_k := \text{GenAndVerify}(L_{k-1})$
18. end while

19. while $k > 1$ do
20.  for $\overrightarrow{s} \in L_k$
21.    VerifySupersequence($\overrightarrow{s}, \overrightarrow{s}.parent_1$)
22.  end for
23.  $k := k - 1$
24. end while
25. return $\bigcup_k \{ \overrightarrow{s} \in L_k | \overrightarrow{s}.RC_{max} \neq \emptyset \lor (\overrightarrow{s}.RC_{max} = \emptyset \land \overrightarrow{s}.C_{max} = \emptyset) \}$ - Return all CSTS patterns.

Steps 15 to 18 of the Algorithm 1 consists of the iterative generation and verification of PI-strong ST sequential patterns of length greater than 2 using the function GenAndVerify shown in Algorithm 2. Specifically, the GenAndVerify function generates all PI-strong ST sequential patterns $L_k$ from PI-strong ST
Algorithm 2 GenAndVerify($L_{k-1}$)

**Input:** $L_{k-1}$ - a set of PI-strong ST sequential patterns of length $k-1$.

**Output:** $L_k$ - a set of PI-strong ST sequential patterns of length $k$.

1: $L_k := \emptyset$
2: for each $s^1_i \in L_{k-1}$ do
3:   $s^1 := s^1_i$’s parent1
4:   for each $s^1_j \in s^1_i$’s $X$ do
5:     $\overrightarrow{s} := s^1_i[1] \rightarrow s^1_i[2] \rightarrow \cdots \rightarrow s^1_i[k-1] \rightarrow s^1_j[k-1]$
6:     $I(\overrightarrow{s}, k) := \bigcup_{e \in I([s^1_i], k-1)} N_{s^1_i}(e)$
7:     $\overrightarrow{s}.PI := \min(\overrightarrow{s}.PI, PR(\overrightarrow{s}, k))$
8:     if $\overrightarrow{s}.PI > \theta$ then
9:       $\overrightarrow{s}.parent1 := s^1_i$; $\overrightarrow{s}.parent2 := s^1_j$
10:      Add $\overrightarrow{s}$ to $\overrightarrow{s}$’s parent1.children; add $\overrightarrow{s}$ to $L_k$
11:   end if
12: end for
13: end for
14: return $L_k$

sequential patterns $L_{k-1}$. To this end, the function uses the first parent, second parent as well as the children list of patterns in $L_{k-1}$. As follows from Lemma 5 (presented in [Maciag et al., 2019] as Lemma 5), a candidate ST sequential pattern $\overrightarrow{s}$ of length $\geq 3$ can be obtained by concatenating all elements of its first parent with the last element of its second parent. 

**Lemma 5** (Construction of an ST sequential pattern from its first parent and second parent [Maciag et al., 2019]). Let $\overrightarrow{s}$ be an ST sequential pattern of length $m \geq 3$ and $s^1_i$ be the first parent of $\overrightarrow{s}$. Then, $\overrightarrow{s} = s^1_i \rightarrow F_m$, where $F_m$ is the last element of parent1($\overrightarrow{s}$), and parent2($\overrightarrow{s}$) = parent2($s^1_i$) $\rightarrow F_m$.

Algorithm 2 proceeds as follows. First the set $L_k$ is initialized. Subsequently, the loop in step 2 iterates over all patterns in $s^1_i \in L_{k-1}$ ($s^1_i$ is the first parent of a new candidate pattern $\overrightarrow{s}$) and the loop in step 4 iterates over all children patterns $s^1_j \in$ parent2($s^1_i$)) of the second parent of $s^1_i$. Each of such $s^1_j$ child patterns constitutes the second parent of a new candidate pattern $\overrightarrow{s}$. Thus, the elements of $\overrightarrow{s}$ are: $\overrightarrow{s} := s^1_i[1] \rightarrow s^1_i[2] \rightarrow \cdots \rightarrow s^1_i[k-1] \rightarrow s^1_j[k-1]$.

After the elements of $\overrightarrow{s}$ are obtained, the set of instances supporting its last element is computed according to step 6 of Algorithm 2 and the $PI$ value of $\overrightarrow{s}$ is calculated according to step 8 of Algorithm 2. If the $PI$ value is greater than the participation index threshold $\theta$, then $\overrightarrow{s}$ is inserted to $L_k$ and appended to the children list of $s^1_i$: children($s^1_i$). Otherwise, $\overrightarrow{s}$ is discarded as not being PI-strong pattern.

The generation of new candidate ST sequential patterns ends when the $GenAndVerify$ function can not generate any new patterns.

---

*We refer the reader to [Maciag et al., 2019] for the proof of Lemma 5*
6.2. The 'Bottom-up' Phase of the CSTS-Miner Algorithm

Algorithm 3 VerifySupersequence($\overrightarrow{s}$, $\overrightarrow{s}_i$)

Input: $\overrightarrow{s}$ - PI-strong ST sequential pattern, whose $RC^{\text{max}}$ set needs to be obtained.

1: if $\overrightarrow{s}.PI \geq \overrightarrow{s}_i.PI - \epsilon$ then
2: if $\overrightarrow{s}_i \notin \overrightarrow{s}.RC^{\text{max}}$ then
3: if $\overrightarrow{s}_i.C^{\text{max}} = \emptyset \lor \text{len}(\overrightarrow{s}) = \text{len}(\overrightarrow{s}_i.C^{\text{max}})$ then
4: if $\overrightarrow{s}_i.C^{\text{max}} = \emptyset \lor \overrightarrow{s}.PI = PI(\overrightarrow{s}_i.C^{\text{max}})$ then
5: Insert $\overrightarrow{s}$ to $\overrightarrow{s}_i.C^{\text{max}}$
6: Insert $\overrightarrow{s}_i$ to $\overrightarrow{s}.RC^{\text{max}}$
7: else if $\overrightarrow{s}.PI > PI(\overrightarrow{s}_i.C^{\text{max}})$ then
8: Remove $\overrightarrow{s}_i$ from $\overrightarrow{s}_k.RC^{\text{max}}$ of all $\overrightarrow{s}_k \in \overrightarrow{s}_i.C^{\text{max}}$
9: $\overrightarrow{s}_i.C^{\text{max}} := \emptyset$
10: Insert $\overrightarrow{s}$ to $\overrightarrow{s}_i.C^{\text{max}}$
11: Insert $\overrightarrow{s}_i$ to $\overrightarrow{s}.RC^{\text{max}}$
12: end if
13: end if
14: end if
15: if $\overrightarrow{s}_i.parent_1 \neq \text{NULL}$ then
16: VerifySupersequence($\overrightarrow{s}$, $\overrightarrow{s}_i.parent_1$)
17: end if
18: if $\overrightarrow{s}_i.parent_2 \neq \text{NULL}$ then
19: VerifySupersequence($\overrightarrow{s}$, $\overrightarrow{s}_i.parent_2$)
20: end if
21: end if
22: return

While the 'top-down' phase generates all PI-strong ST sequential patterns, the 'bottom-up' phase of Algorithm 1 starts in step 19 and is entirely dedicated to calculation of these PI-strong ST sequential patterns which are PI-strong CSTS patterns. The verification of PI-strong ST sequential patterns as being CSTS patterns starts from the set $L_k$ of the longest patterns and is iteratively continued for the subsequent sets of patterns $L_{k-1}, L_{k-2}, \ldots, L_2$.

The function VerifySupersequence presented in Algorithm 3 receives two ST sequential patterns $\overrightarrow{s}$ and $\overrightarrow{s}_i$ and verifies if $\overrightarrow{s}$ is a CSTS pattern of $\overrightarrow{s}_i$. To this end, function VerifySupersequence applies Definition 12 and Theorem 1. Specifically, function VerifySupersequence conducts the following steps:

1. Checks if the $PI$ value of $\overrightarrow{s}$ is greater than the $PI$ value of $\overrightarrow{s}_i$ minus approximation margin $\epsilon$ (in step 1). This fulfils the first condition of Definition 12.

2. Checks if $\overrightarrow{s}_i$ already belongs to the $RC^{\text{max}}$ list of $\overrightarrow{s}$ (in step 2). Due to construction of MAX-Tree, it can happen that the function VerifySupersequence will be invoked multiple times for the same two sequences $\overrightarrow{s}$ and $\overrightarrow{s}_i$. Thus, the check prevents the situation when $\overrightarrow{s}_i$ is added multiple times to the list $RC^{\text{max}}(\overrightarrow{s})$. 

20
3. Verifies whether there is no pattern of $s_i^\vec{s}$ in the set $C_{\max}(s_i^\vec{s})$ or the length of $\vec{s}$ equals the length of the patterns in $C_{\max}(s_i^\vec{s})$. In such a case, the two situations are possible:

- Either $C_{\max}(s_i^\vec{s}) = 0$ or the PI value of $\vec{s}$ equals the PI values of $C_{\max}(s_i^\vec{s})$ patterns. In any case, $\vec{s}$ is inserted to $C_{\max}(s_i^\vec{s})$ and $s_i^\vec{s}$ is inserted to $RC_{\max}(s_i^\vec{s})$.

- Alternatively, if the PI value of $\vec{s}$ is greater than the PI values of patterns in $C_{\max}(s_i^\vec{s})$, then $s_i^\vec{s}$ is removed from the $RC_{\max}$ lists of all patterns in $C_{\max}(s_i^\vec{s})$ and $C_{\max}(s_i^\vec{s})$ is set to be empty. Next, $\vec{s}$ is added to $C_{\max}(s_i^\vec{s})$ and $s_i^\vec{s}$ is added to $RC_{\max}(\vec{s})$. This set fulfils the second condition of Definition 12.

If the PI value of $\vec{s}$ is greater than the PI value of $s_i^\vec{s}$ minus approximation margin $\varepsilon$, then $VerifySupersequence$ function is recursively invoked for $\vec{s}$ and the parent patterns $parent_1(s_i^\vec{s})$, $parent_2(s_i^\vec{s})$ of $s_i^\vec{s}$ to verify whether $\vec{s}$ is also their CSTS pattern. Otherwise, as follows from Theorem 1, $\vec{s}$ can not be a CSTS pattern of any of parent patterns $parent_1(s_i^\vec{s})$, $parent_2(s_i^\vec{s})$ of $s_i^\vec{s}$. Thus, invocations of $VerifySupersequence \vec{s}, parent_1(s_i^\vec{s})$ and $VerifySupersequence \vec{s}, parent_2(s_i^\vec{s})$ are skipped.
\[ \theta = 0.25, \varepsilon = 0.25 \]

Figure 2: The complete MAX-Tree generated with parameters \( \theta = 0.25 \) and \( \varepsilon = 0.25 \) for the dataset presented in Figure 1 (all boxes represent PI-strong ST sequential patterns, while blue boxes represent patterns being also PI-strong CSTS patterns; PI values are given in parentheses next to the patterns).
The complete MAX-Tree created for the dataset shown in Figure 1 is presented in Figure 2. The tree is created by Algorithm 1 using the following input parameters: spatial threshold value $R = 10$, time window threshold value $T = 20$, participation index threshold value $\theta = 0.25$, approximation margin value $\varepsilon = 0.25$. All patterns in the tree are PI-strong ST sequential patterns; however, only blue boxes represent those of them, which are also PI-strong CSTS patterns.

For the pattern $\vec{s} = B \rightarrow B \rightarrow C$, the set of its CSTS patterns is $C^{\text{max}}(\vec{s}) = \{A \rightarrow B \rightarrow B \rightarrow C \rightarrow E \rightarrow C\}$, while the minimal proper supersequence of $\vec{s}$ among the set of PI-strong CSTS patterns returned by Algorithm 1 is $\vec{s}_1 = B \rightarrow B \rightarrow C \rightarrow E$. Let us consider how one can approximate the participation index value of pattern $\vec{s}$ given the set of all PI-strong CSTS patterns presented in Figure 2. Since the set of PI-strong CSTS patterns contains more than one supersequence of $\vec{s}$, then the value of participation index of $\vec{s}$ is $\text{PI}(\vec{s}) \leq \text{PI}(\vec{s}_1) + \varepsilon = 0.375 + 0.25 = 0.625$. In fact, the exact PI value of $\vec{s}$ equals $\text{PI}(\vec{s}) = 0.5$.

7. Experiments

In this section, we first review datasets used for the experiments and describe our experimental setup. Then we provide results of the comparison of the proposed CSTS-Miner algorithm with the STS-Miner (Huang et al., 2008), CST-SPMiner (Maciag et al., 2019), STBFM (Maciag et al., 2019) and CSTPM (Mohan et al., 2012) algorithms.

7.1. Selected Dataset

For the experiments with the proposed CSTS-Miner algorithm we selected two publicly available datasets, each of which consists of crime event incidents.

7.1.1. Pittsburgh Police Incident Blotter Dataset

The first dataset selected for the experiments is Pittsburgh Police Incident Blotter Dataset that contains crime incidents collected by the Police Department of Pittsburgh City over the period 31.12.1989 - 31.12.2019 (Pittsburgh Police Department, 2020). The dataset was validated according to the Uniform Crime Reporting (UCR) standards (UCR program, 2020) and consists of such attributes as: incident time, incident location (defined by street name and number), incident neighborhood, incident type, description of offense, incident longitude and latitude locations. For the purposes of experiments we selected the following attributes of the dataset: incident type, incident time, longitude and latitude which are directly used by the proposed CSTS-Miner algorithm.

In the experiments, we use only crime incidents reported between 01.01.2017 and 31.12.2019. The number of crime incidents reported over this period is 122,895; however, approximately 40% of them contain missing values for one of the selected attributes: incident type, geographical location or incident time. Thus, we decided to remove such incidents. The resultant dataset contains 72,867 crime incidents.
event incidents of 236 unique incident types. All of these 236 incident types are selected as event type set $F$. To the most frequent incident types belong: theft from auto, simple assault, public drunkenness, criminal mischief or harassment. The attribute incident time (which specifies incident occurrence time with exact occurrence date and a timestamp given in hours, minutes and seconds) is transformed into the number of minutes that passed from the timestamp 01.01.2017 00:00. Thus, the time window parameter $T$ used by the CSTS-Miner algorithm is specified in minutes. In Table 3 we present the characteristic of the resultant dataset.

In Figure 3 we present the location of the first two thousand crime incidents of ten most frequent incident types from the resultant Pittsburgh Police Incident Blotter Dataset.

Table 3: The characteristic of the resultant Pittsburgh Police Incident Blotter Dataset.

| Parameter                     | Value                |
|-------------------------------|----------------------|
| No. of incident types ($|F|$) | 236                  |
| No. of incident instances ($|D|$) | 72,867               |
| Avg. no. of incidents per type | 309                  |
| Median no. of incidents per type | 26                  |
| Std. of no. of incidents per type | 784                 |
| Min. no. of instances in a type | 1                   |
| Max. no. of instances in a type | 6201                |

Figure 3: The first two thousand crime incidents of ten most frequent incident types from the resultant Pittsburgh Police Incident Blotter Dataset.
7.1.2. Boston Crime Incident Reports Dataset

The second of the selected datasets is Boston Crime Incidents Reports Dataset provided by the Boston Police Department (Boston Police Department, 2014). The dataset was collected over the period 08.07.2012 - 10.08.2015. However, in the experiments, we extracted only crime incidents that occurred between 01.01.2014 - 31.12.2014. The Boston Crime Incidents Reports Dataset contains several attributes, such as: incident location, incident time, incident type, used weapon type (such as, for example, unarmed or firearm) shooting presence, police shift or occurrence district and occurrence area. Similarly to the Pittsburgh Police Incident Blotter Dataset, for the experiments we selected only attributes: incident location (given by longitude and latitude), incident time and incident type. Since the attribute incident type does not contain only crime incident types, but also other incident types, such as medical assist or property found, we preprocessed the dataset to obtain incidents of all 26 crime event types present in the dataset. The examples of event types are: aggravated assault, arson, auto theft or drug charges.

Additionally, to better analyze the results that can be obtained with CSTS-Miner, we selected incidents of only the ten least frequent crime types in the complete dataset to create the reduced dataset. These crime types are violation of liquor laws, operating under influence, manslaughter, homicide, harassment, gambling offense, embezzlement, crimes against children, bomb, arson.

In Table 4, we present the characteristic of the complete dataset, while in Table 5 the characteristic of the reduced dataset is shown. Since there are only 26 crime event types in the complete dataset, we decide to present the number of incidents of each type in the histogram shown in Figure 4.

| Parameter                  | Value     |
|----------------------------|-----------|
| No. of incident types (|F|) | 26        |
| No. of incident instances (|D|) | 40,545    |
| Avg. no. of incidents per type | 1,559    |
| Median no. of incidents per type | 527      |
| Std. of no. of incidents per type | 2,176    |
| Min. no. of instances in a type | 1        |
| Max. no. of instances in a type | 8,575    |

7.2. Experimental Setup

In our experiments, the spatial distance threshold R of a neighborhood of an event instance e is specified in meters. However, the locations of event instances in the obtained datasets are specified using the longitude and latitude coordinates. Thus, we apply the following procedure to transform the distance between two event instances e1, e2 ∈ D into meters. First, each coordinate (either longitude or latitude) of an instance e is converted into radians according
Table 5: The characteristic of the reduced Boston Crime Incident Reports Dataset.

| Parameter                        | Value         |
|----------------------------------|---------------|
| No. of incident types ($|F|$) | 10            |
| No. of incident instances ($|D|$) | 896           |
| Avg. no. of incidents per type   | 90            |
| Median no. of incidents per type | 72            |
| Std. of no. of incidents per type| 83            |
| Min. no. of instances in a type  | 1             |
| Max. no. of instances in a type  | 245           |

Figure 4: Incidents count per crime type in the complete Boston Crime Incident Reports Dataset used for experiments.

to Eq. (3) in which, $e.\text{lat}$ refers to the latitude coordinate and $e.\text{lon}$ refers to the longitude coordinate of instance $e$, respectively. Next, the distance in meters between two instances is obtained according to Eq. (4). In Eq. (4), earthRadius denotes the radius of Earth in kilometers.

\[
\text{rad}_{e.\text{lat}} = \frac{e.\text{lat} \cdot \pi}{180}; \quad \text{rad}_{e.\text{lon}} = \frac{e.\text{lon} \cdot \pi}{180}.
\] (3)
\[
D_{\text{slat}} = \sin \left( \frac{(\text{rad}_e \cdot \text{lat}_2 - \text{rad}_e \cdot \text{lat}_1)}{2} \right),
\]
\[
D_{\text{slon}} = \sin \left( \frac{(\text{rad}_e \cdot \text{lon}_2 - \text{rad}_e \cdot \text{lon}_1)}{2} \right),
\]
\[
\text{Dist}_{(e_1, e_2)} = 2 \cdot \text{earthRadius} \cdot 1000 \cdot \arcsin \left( \sqrt{D_{\text{slat}}^2 + D_{\text{slon}}^2 \cdot \cos(\text{rad}_e \cdot \text{lat}_1) \cdot \cos(\text{rad}_e \cdot \text{lat}_2)} \right). \tag{4}
\]

The implementations of all algorithms selected for experiments are prepared in C++. We ran experiments using a computer equipped with Apple M1 processor and 16 GB of RAM memory. Our implementations of the algorithms (STS-Miner, STBFM, CSTPM, CST-SPMiner, CSTS-Miner) are available at the GitHub repository.\footnote{https://github.com/piotrMaciag32/CSTS-Miner}

7.3. Results of Experiments

In the experiments, we compare our proposed CSTS-Miner with the four other algorithms: STS-Miner applying participation index measure (Huang et al. 2008), STBFM (Maciąg & Bembenik 2019), CSTPM (Mohan et al. 2012) which all discover PI-strong ST sequential patterns and CST-SPMiner (Maciąg et al. 2019) discovering PI-strong closed ST sequential patterns.

We aim to measure the number of discovered patterns by each of the algorithms and their computation times for each of the selected datasets. The main obtained results for each dataset are presented in Tables 6, 7 and 8. The results presented in these tables were obtained for the following input parameters of the five compared algorithms:

- For the Pittsburgh Police Incident Blotter Dataset: \( R = 350 \) meters, \( T = 11520 \) (8 days), \( \theta = \{0.33, 0.01, \ldots, 0.25\} \), \( \varepsilon = \{0.025, 0.05, 0.075\} \).
- For the complete Boston Crime Incidents Report Dataset: \( R = 300 \) meters, \( T = 5760 \) minutes (4 days), \( \theta = \{0.055, 0.05, \ldots, 0.015\} \), \( \varepsilon = \{0.05, 0.1, 0.15\} \).
- For the reduced Boston Crime Incidents Report Dataset: \( R = 500 \) meters, \( T = 43200 \) minutes (30 days), \( \theta = \{0.01, 0.0095, \ldots, 0.005\} \), \( \varepsilon = \{0.05, 0.1, 0.15\} \).

Table 6 presents the results for the Pittsburgh Police Incident Blotted dataset. As it can be noted from the table, CSTS-Miner can discover much fewer patterns for all three selected values of its approximation margin \( \varepsilon \) parameter than the other four selected algorithms. For example, for the participation index threshold \( \theta = 0.26 \), there are 143 666 PI-strong ST sequential patterns and 100 235 PI-strong closed ST sequential patterns, while the number of PI-strong CST patterns discovered for the approximation threshold value \( \varepsilon = 0.1 \) is only 58 519. As it can be noted from Table 6, the increasing values of approximation margin \( \varepsilon \) can result in a significant increase of computation times of CSTS-Miner.
For example, for $\theta = 0.25$ STBFM and CST-SPMiner both executed in 207 seconds, while CSTS-Miner for $\varepsilon = 0.025$ parameter executed in 253 seconds and for $\varepsilon = 0.075$ parameter executed in 1744. Please note that for $\theta = 0.25$ computations for STS-Miner and CSTPM were too long to be obtained.

The slightly different results were presented in Table 7 for the complete Boston Crime Incident Report dataset. In the case of this dataset, it was possible to obtain a similar reduction in the number of discovered patterns as in the case of the Pittsburgh Police Incident Blotted dataset. For example, for the participation index threshold $\theta$ equal to 0.015, the numbers of PI-strong ST sequential patterns and PI-strong closed ST sequential patterns are 2819490 and 2040303, respectively. For the same value of $\theta$ parameter and $\varepsilon = 0.15$, CSTS-Miner is able to provide as many as 1171955 PI-strong CSTS patterns. Thus, the reduction in the number of patterns is 58% when compared to the STBFM algorithm as well as 43% when compared to the CST-SPMiner algorithm.

Finally, in Table 8 we present the results obtained for the reduced Boston Crime Incident Report dataset. The reduction in the number of discovered patterns is even more impressive in the case of this dataset. For the values of participation index threshold $\theta = 0.005$ and approximation margin $\varepsilon = 0.15$, CSTS-Miner provided 65899 PI-strong CSTS patterns. For the same $\theta$ value, the numbers of PI-strong ST sequential patterns and PI-strong closed ST sequential patterns discovered are 228285 and 76894 patterns, respectively. Thus, the reduction in the number of discovered patterns by CSTS-Miner when compared to STS-Miner, CSTPM, STBFM is 71% and when compared to CST-SPMiner is 24%. However, please note that the computation time for the reduced dataset can be significantly higher in the case of the CSTS-Miner algorithm than in the cases of the STBFM and CST-SPMiner algorithms. Please also note that for the reduced Boston Crime Incident Report dataset, CSTPM executes much longer than the other algorithms.

In Figure 5, we provide the plots presenting the percent of the number of discovered PI-strong CSTS patterns to the number of discovered PI-strong ST sequential patterns. As it can be noted from the presented plots, the percent ranges between 15% and 90%. It was possible to obtain minimal values of the percent (around 15%) for the reduced Boston Crime Incidents Report dataset when the spatial threshold $R = 600$ meters as well as temporal window $T = 28800$ minutes were applied and the $\theta$ threshold was equal to the values in the range $0.29 - 0.28$. In the case of both Pittsburgh Crime Incident Blotter and complete Boston Crime Incidents datasets, for the smaller values of the $\theta$ threshold ($< 0.3$) and the approximation margin $\varepsilon$ equal to 0.2, the obtained percent is usually below 50%. Interestingly, not always the smaller value of the $\theta$ threshold resulted in a more significant reduction of the number of discovered patterns. For example, for the Pittsburgh Crime Incident Blotter dataset and parameters $R = 350$ meters, $T = 11520$ minutes as well as approximation margin $\varepsilon$ equal to 0.2 or 0.1 the smallest percent was obtained for the $\theta = 0.28$.

R = 500 meters, T = 43200 (30 days)
In Figure 5 we provide the plots presenting the percent of the number of PI-strong CSTS patterns discovered by the CSTS-Miner algorithm to the number of PI-strong ST sequential patterns discovered by the STS-Miner, STBFM and CSTPM algorithms.

Figure 5: Percent of the number of PI-strong CSTS patterns discovered by the CSTS-Miner algorithm to the number of PI-strong ST sequential patterns discovered by the STS-Miner, STBFM and CSTPM algorithms.

In Figure 6, we provide the plots presenting the percent of the number of PI-strong CSTS patterns discovered by the CSTS-Miner algorithm to the number of PI-strong closed ST sequential patterns. As follows from Lemma 1, for $\varepsilon = 0$ the set of PI-strong CSTS patterns is equal to the set of PI-strong closed ST sequential patterns. However, for the greater values of the $\varepsilon$ parameter (such as, for example 0.1 or 0.2), CSTS-Miner is able to provide as few as 50% of the number of PI-strong closed ST sequential patterns discovered by CST-SPMiner. Importantly, even for the smaller values of the $\varepsilon$ parameter (such as, for example, 0.01), CSTS-Miner is able to provide as few as 70% of the number of patterns provided by CST-SPMiner (as it is shown, for example, in the plots for the complete Boston Crime Incidents Report dataset presented in Figure 6).

To summarize, the plots presented in Figures 5 and 6 show that the CSTS-
Figure 6: Percent of the number of PI-strong CSTS patterns discovered by the CSTS-Miner algorithm to the number of PI-strong closed significant ST sequential patterns discovered by the CST-SPMiner algorithm.

Our next experiment aimed to compare the computation times of steps 1 - 18 (phase "top-down") and steps 19 - 25 (phase "bottom-up") of Algorithm 1. As previously noted, the "top-down" phase is responsible for generating all PI-strong ST sequential patterns, while the "bottom-up" phase calculates those of them which are also PI-strong CSTS patterns.

In Figure 7, we present the comparison of computation times (in logarithmic scale) of both phases obtained for the Pittsburgh Police Incident Blotter dataset. Please note that for the smaller values of the approximation margin \( \varepsilon \) (such as...
Figure 7: Computation time in seconds of the "top-down" phase (steps 1 - 17) and the "bottom-up" phase (steps 18 - 24) of Algorithm 1 for the Pittsburgh Police Incident Blotter Dataset. Please note the logarithmic scale for the computation time.

\( \varepsilon = 0.025 \), the computation times for the "top-down" phase are more significant than for the "bottom-up" phase. However, with the increasing values of \( \varepsilon \) and for smaller values of \( \theta \) threshold, the computation time of the "bottom-up" phase can increase significantly. For example, for the parameters \( \varepsilon \) equal 0.1 and \( \theta \) equal 0.25, the computation time of the "bottom-up" phase of Algorithm 1 can be up to four times longer than the computation time of the "top-down" phase for the same values of these parameters.

7.4. Selection of Representative Patterns

In this subsection, we provide some interesting examples of discovered sequential patterns of different types of crimes. To do this end, we ran CSTS-Miner using the Pittsburgh Police Incident Blotter Dataset with the following parameters: \( R = 300, T = 11520 \) minutes (8 days), \( \varepsilon = 0.05, \theta = 0.3 \).

The examples of interesting resultant patterns include:

1. public_drunkenness \( \rightarrow \) robbery/ bank/ knife (PI = 0.5).
2. public_drunkenness \( \rightarrow \) robbery/ bank/ strongarm (PI = 0.44).
3. simple_assault/ injury \( \rightarrow \) public_drunkenness \( \rightarrow \) public_drunkenness \( \rightarrow \) all_other_offenses (expt_traff) \( \rightarrow \) fail_ disord_per_to_disperse (PI = 0.30).
4. simple_assault/ injury \( \rightarrow \) public_drunkenness \( \rightarrow \) robbery/ bank/ _strongarm (PI = 0.33).
5. robbery/ highway/ gun \( \rightarrow \) sale/ use_of_air_rifles (PI = 0.5).

Patterns 1 and 2 could provide essential information about types of banks robberies. Pattern 1 states that half of the bank robberies using a knife were conducted within 300 meters and 8 days from the reported public drunkenness incidents. On the other hand, pattern 2 communicates that 44% of all bank robberies using weapon (strongarm) occurred within 300 meters and 8 days from the reported public drunkenness incidents. The other interesting example is pattern 4, which states that half of the usage of air rifles occurred within 300 meters and 8 days from the highway robbery.
8. Conclusion

In this article, we offered a new type of ST sequential patterns called \( \varepsilon \)-constricted ST sequential patterns (CSTS patterns) and we thoroughly analyzed their theoretical properties. Specifically, we showed that the set of CSTS patterns is a subset of the set of closed ST sequential patterns and that each CSTS pattern is also a closed ST sequential pattern. Moreover, we showed that given the set of PI-strong CSTS patterns one can obtain the set of all PI-strong ST sequential patterns and approximate participation index of each of them with the approximation margin \( \pm \varepsilon \). We also offered a new algorithm called CSTS-Miner that discovers all PI-strong CSTS patterns. To this end, CSTS-Miner adapts the MAX-Tree structure for the more efficient candidate patterns generation. The proposed MAX-Tree is generated in the two main phases of CSTS-Miner: the first one called "top-down" in which all PI-strong ST sequential patterns are generated using the breadth-first strategy, and the second one called "bottom-up" which calculates PI-strong ST sequential patterns being CSTS patterns. We analyzed properties and computation times of CSTS-Miner.

The experiments with the CSTS-Miner algorithm were conducted using two crime-related datasets for the cities of Boston and Pittsburgh: the Pittsburgh Police Incident Blotter Dataset and the Boston Crime Incident Reports Dataset. Each of the selected datasets consists of various types of crime and numerous event instances. Moreover, to better verify the capabilities of the proposed algorithm, we extracted a reduced dataset from the complete Boston Crime Incident Reports dataset. The resultant reduced dataset contains 10 least frequent crime event types and 896 event instances.

In the experimental evaluation, we compared the results obtained with the proposed CSTS-Miner algorithm with four other state-of-the-art algorithms: STS-Miner (Huang et al., 2008), CSTPM (Mohan et al., 2012), STBFM (Maciąg & Bembenik, 2019) and CST-SPMiner (Maciag et al., 2019). The STS-Miner, CSTPM and STBFM algorithms discover PI-strong ST sequential patterns, whereas CST-SPMiner discovers PI-strong closed ST sequential patterns. Each of the selected algorithms, as well as the proposed algorithm, use the participation index to measure the significance of the discovered patterns. As we presented in the experiments, in the case of the Pittsburgh Police Incident Blotter Dataset and in the cases of the complete and reduced Boston Crime Incident Reports Dataset, CSTS-Miner can return much fewer patterns than the other selected algorithms. In particular, in the case of the Pittsburgh Police Incident Blotter Dataset, CSTS-Miner provides up to 60% fewer patterns when compared to STBFM and up to 50% fewer patterns when compared to CST-SPMiner. Similarly, for the complete Boston Crime Incident Reports Dataset, CSTS-Miner provides up to 60% fewer patterns when compared to STBFM and up to 40% fewer patterns when compared to CST-SPMiner. For the reduced Boston Crime Incident Reports Dataset, CSTS-Miner provides up to 85% fewer patterns than STBFM and up to 50% fewer patterns than CST-SPMiner.
