ABSTRACT

It is widely believed that the primary X-ray emission of AGN is due to the Comptonization of optical-UV photons from a hot electron corona, while the origin of the ‘soft-excess’ is still uncertain and matter of debate. A second Comptonization component, called warm corona, was therefore proposed to account for the soft-excess, and found in agreement with the optical-UV to X-ray emission of a sample of Seyfert galaxies. In this context, we exploit the broad-band XMM–Newton and NuSTAR simultaneous observations of the Seyfert galaxy NGC 4593 to further test the so-called ‘two corona model’. The NGC 4593 spectra are well reproduced by the model, from the optical/UV to the hard X-rays. Moreover, the data reveal a significant correlation between the hot and the warm corona parameters during our monitoring campaign.

Key words: galaxies: active – galaxies: Seyfert – X-rays: galaxies – X-rays: individuals: (NGC 4593).

1 INTRODUCTION

According to the standard paradigm, the intrinsic X-ray emission of active galactic nuclei (AGNs) is the result of an inverse-Compton process in which seed optical-UV photons arising from the accretion disc interact with a compact distribution of thermal electrons, the hot corona (e.g. Haardt & Maraschi 1991, 1993; Haardt, Maraschi & Ghisellini 1994). This mechanism accounts for the observed power law like X-ray continuum. The optical depth ($\tau_{hc}$) and the temperature of the hot coronal electrons ($kT_{hc}$) affect the spectral shape of the primary continuum. On the other hand, since the energy gain of the up-scattering disc photons is limited, a high-energy cut-off is expected (Rybicki & Lightman 1979). This high-energy cut-off can be therefore interpreted as the signature of thermal Comptonization itself, thus many efforts were spent to measure this spectral feature (e.g. Nicastro et al. 2000; Perola et al. 2000; De Rosa, Fabian & Piro 2002; Dadina 2007; Molina et al. 2009, 2013; Malizia et al. 2014). More recently, thanks to its unprecedented sensitivity above 10 keV, NuSTAR allowed for a large number of cut-off measurements (e.g. Fabian et al. 2015, 2017; Tortosa et al. 2018).

On the other hand, in the soft X-rays, an excess of photons rising below 1 keV above the extrapolated high-energy emission is commonly observed in a large percentage of AGN (e.g. Walter & Fink 1993; Gierliński & Done 2004; Page et al. 2004; Crummy et al. 2006; Ponti et al. 2006; Bianchi et al. 2009). This spectral feature, also called soft-excess, has been the object of many speculations (e.g. Done et al. 2012) and, at present, its origin is still a matter of debate. Different models accounting for blurred ionized reflection, ionized absorption or partial covering, and thermal Comptonization have been proposed (e.g. Magdziarz et al. 1998; Crummy et al. 2006; Done et al. 2007; Done et al. 2012; Jin et al. 2012).

In this context, Petrucci et al. (2013) studying the rich data set of the XMM–Newton–INTEGRAL multiwavelength campaign (Kaastra et al. 2011) found that the spectrum of Mrk 509 can be described by a two-corona model: beside a hot and optically thin corona accounting for the hard X-rays, a warm ($kT \sim 1$ keV) and optically thick ($\tau \sim 15$) corona was in fact able to reproduce the Mrk 509 optical-UV emission and its soft-excess. The two-corona model was then adopted in analysing the high-signal-to-noise (S/N) data belonging to the multiwavelength campaign on NGC 7469 (Middei et al. 2018). Porquet et al. (2018), working on high-quality data of Ark 120, also found that the source emission is dominated by two temperature Comptonization processes. Finally, the two-corona model was successfully tested on a larger sample of Seyfert galaxies.
Figure 1. Residuals of the XMM–Newton and NuSTAR data to a power model fitted in the 4–10 keV energy range and extrapolated down to 0.3 keV. A prominent and variable soft-excess is clearly present below 2–3 keV. Black, red, green, blue, magenta, and cyan colours refer to obs. 1a, obs. 1b, obs. 2, obs. 3, obs. 4, and obs. 5, respectively. This colour code is adopted in the whole paper.

(Petrucci et al. 2018), though the energy coupling between the two coronae and the outer disc also suggests that part of the optical-UV flux could be produced by the outer standard disc (Kubota & Done 2018).

The multiwavelength campaign on NGC 4593 provides a further excellent data set for testing the two-corona model. The source was observed simultaneously by XMM–Newton and NuSTAR, thus data extend from the optical-UV band up to the hard X-rays. A phenomenological spectral analysis of the campaign is reported in Ursini et al. (2016), hereafter P1. In P1 the source was found to be variable, both in flux and spectral shape, and the characteristic softer-when-brighter behaviour was observed. During the observational campaign, a strongly variable high-energy cut-off was measured ($E_{\text{cut-off}}$ from 90$^{+30}_{-20}$ keV to $>$700 keV), and the spectral index varied on time-scales down to 2 d between 1.6 and 1.8. A prominent Fe Kα line was measured, best explained as the superposition of a narrow constant component and a broader component likely arising, respectively, from distant cold material and from circumnuclear matter at about $\lesssim40$ $R_{\text{gas}}$ ($R_{\text{gas}} = 2GM/c^2$). In agreement with past studies on this source, a warm absorber consistent with a two-phase ionized outflow was needed to reproduce the data set. From the analysis of RGS data, an additional photoionized component in emission was required to fit the data. Furthermore, NGC 4593 showed a remarkable and variable soft-excess during the monitoring, see Fig. 1. In this work, exploiting the high-S/N data of the NGC 4593 observational campaign, we test Comptonization, and, in particular, the two-corona model on this source. The standard cosmology $\Lambda$CDM with $H_0 = 70$ km s$^{-1}$ Mpc$^{-1}$, $\Omega_m = 0.27$, $\Omega_\Lambda = 0.73$, is adopted.

2 DATA

The data set analysed here belongs to the joint XMM–Newton and NuSTAR monitoring program on NGC 4593, and consists of 5 $\times$ ~20 ks simultaneous observations. The monitoring covers the time period between 2014 December 29 2014 and 2015 January 06 2015, with consecutive pointings being about 2 d apart (see Table 1).

XMM–Newton data of NGC 4593 were obtained with the EPIC cameras (Strüder et al. 2001; Turner et al. 2001) in Small Window mode with the medium filter applied. Because of its larger effective area with respect to the two MOS cameras, we only used the results for the PN instrument. Data are processed using the XMM–Newton Science Analysis System (SAS, version 16.1.0). The choice of source extraction radius and the screening for high background time intervals are performed by an iterative process that maximizes the S/N, as in Piconcelli et al. (2004). The source radii span between 20 and 40 arcsec. The background is then extracted in a blank region close to the source using a region with a radius of 50 arcsec. We then rebinned all the spectra to have at least 30 counts for each bin, and without oversampling the instrumental energy resolution by a factor larger than 3. Moreover, for this analysis we take advantage of data provided by the Optical Monitor (OM; Mason et al. 2001), on-board XMM–Newton. This instrument observed NGC 4593 with the filters U (3440 Å), UVW1 (2910 Å), and UVW2 (2120 Å) for all the pointings of the campaign. Data provided by the OM are extracted using the on-the-fly data processing and analysis tool RISA, the Remote Interface SAS Analysis. To convert the spectral points into convenient format to be analysed with XSPEC (Arnaud 1996), we used the standard task om2pha. The light curves for the OM various filters are reported in Fig. 2.

NuSTAR data were reduced taking advantage of the standard pipeline (nupipeline) in the NuSTAR Data Analysis Software (NUSTARDAS release: nustardas_14Apr16_v1.6.0, part of the HEASOFT distribution). The adopted calibration data base is 20171204. High scientific products were then obtained using the standard nuproducts routine for both the hard X-ray detectors FPMA/B carried on the NuSTAR focal plane. A circular region with a radius of 75 arcsec is used to extract the source spectra, while the background is extracted from a blank area with the same radius, close to the source. We have then binned the NuSTAR spectra in order to have an S/N greater than 5 in each spectral channel, and to not oversample the resolution by a factor greater than 2.5.

Light curves and hardness ratios are discussed and shown in P1 to which we refer the reader. In all the observations of the campaign both spectral and flux variability can be observed. In particular, in the first pointing variability is very significant (see Fig. 3), thus we split observation one in two segments of 10 ks each. Then similarly to P1, we are left with six spectra for testing the two-corona model.

Finally, we notice that in other multiwavelength campaigns different photon index estimates were obtained from XMM–Newton and NuSTAR data in AGN and X-ray binaries (e.g. Cappi et al.

Table 1. For each satellite the observation ID, the start date and the net exposure time are reported.

| NuSTAR        | 60001149010 | 2015-01-06 | 21       |
We performed the spectral analysis using XSPEC. In the forthcoming fits a free cross-calibration constant is used to take into account residual calibration problems between {	extsc{xmm--newton}} and NuSTAR data. The NuSTAR modules are in good agreement with each other (~2 per cent), and the detectors of both satellites agree within \( \lesssim 10 \) per cent. In this analysis we take into account the absorption due to the Galactic hydrogen column through the XSPEC model \textit{phabs} for which the Galactic column density is set to \( N_H = 1.89 \times 10^{20} \text{cm}^{-2} \) (Kalberla et al. 2005). During the fitting procedure, the Galactic \( N_H \) is kept fixed.

**Optical-UV:** This spectral investigation extends from the optical-UV domain up to hard X-rays, thus we have to consider the broad-line region (BLR) contribution. In fact, the BLR is responsible for the so-called small blue bump at about 3000 Å. We account for this component using an additive table in XSPEC. A detailed description of this table for the case of NGC 5548 is provided by Mehdipour et al. (2015). While performing the fit we let free to vary (but tied among the pointings) the normalization of this table. From the fit, a flux of \( (1.2 \pm 0.1) \times 10^{-11} \text{erg s}^{-1} \text{cm}^{-2} \) was found for this component. Finally, we include the effect of the Galactic extinction using the \textit{redden} model in XSPEC. The reddening is kept fixed while fitting the data to the value \( E(B-V) = 0.021 \) (Schlafly & Finkbeiner 2011).

**Soft X-rays:** The \textit{nthcomp} model (Zdziarski, Johnson & Magdziarz 1996; Życki, Done & Smith 1999) is used to reproduce the soft-excess. This model provides a thermally Comptonized continuum and the high-energy roll-over is parametrized by the electron temperature. In the fitting procedure the normalization, the photon index, and the warm electron temperature \( kT_{\text{we}} \) are free to vary between the observations. In \textit{nthcomp}, we assumed the seed photons to arise from a disc-like blackbody. As a first step, the seed photon temperature \( (kT_{\text{sb}}) \) was fitted for each observation. However, since the \( kT_{\text{sb}} \) were consistent with being constant, we fit the \( kT_{\text{sb}} \) temperature tying its value among the various pointings. In P1 two ionized warm absorbers and a photoionized emission component were confirmed to contribute to the NGC 4593 soft X-ray emission, thus, in this modelling, we account for these spectral components adopting tables in \textsc{xspect} (atable(WA1), atable(WA2), and atable(REFL)). These tables are computed thanks to the spectral synthesis code \textsc{cloudy} (v13.03; Ferland et al. 2013). The best-fitting values for these components are shown in P1 (its section 3.1; Table 3). In this paper, we adopt the same best-fitting values published in P1 keeping them frozen during the fit. Moreover, it is well known that in the soft band some spectral features cannot be directly attributed to the targeted source. For instance, spectral features close to the Si K-edge \((E = 1.84 \text{keV})\) and the Au M-edge \((E \sim 2.4 \text{keV})\) may be an artefact of the detector systematic calibration uncertainties. To avoid these issues, we ignored the spectral bins in the energy range 1.8–2.4 keV (see e.g. Kastra et al. 2011; Di Gesu et al. 2015; Ursini et al. 2015; Cappi et al. 2016; Middei et al. 2018). However, after this procedure, a line-like feature still remains in the \textit{pn} spectra, and even if very weak \((E_W = 8 \text{eV})\), it is significant in terms of \( \chi^2 \), as a consequence of the high number of counts in the soft band. A single narrow Gaussian line untied and free to vary among the observations at \( \sim 0.6 \text{keV} \) is enough to correct this residual narrow feature (see also e.g. Kastra et al. 2011; Di Gesu et al. 2015; Ursini et al. 2015; Cappi et al. 2016).

**Hard X-rays:** The primary continuum in the 2–79 keV band is then described by a second \textit{nthcomp} where the seed photons are assumed to arise from a disc-blackbody whose temperature is fixed to the \textit{nthcomp} model of the soft X-rays. On the other hand in P1, the hard X-ray emission of NGC 4593 displays additional complexities. In fact, a prominent Fe K\( \alpha \) is found to be the superposition of a relativistically broadened and narrow components, thus we add to the primary Comptonization continuum the reflection models \textit{relxillcp} and \textit{xillvercp} (García et al. 2014; Dauser et al. 2016). These models self-consistently incorporate fluorescence emission lines and the corresponding accompanying Compton reflection hump. Then, \textit{xillvercp} supplies the narrow-line component, while \textit{relxillcp} accounts for the relativistic effects and the broad-line component. We assumed the same iron abundance \( A_{Fe} \) for \textit{xillvercp} and \textit{relxillcp}, and, in the fitting procedure, we let this parameter free to vary but tied between the various pointings. We tied the photon index and the electron temperature of the hot corona \( kT_{\text{be}} \) between \textit{nthcomp} and \textit{relxillcp}, while the normalizations are free to vary and untied between models and observations. In P1 the narrow-line component coming from cold material is found to be constant among the various observations thus for \textit{xillvercp} the photon index and normalizations are free to vary but tied between the observations. Moreover, since the source is spectrally variable, there is no reason to assume that the radiation incident on the distant reflector is the same as that from the primary component. We therefore allow for different photon index between \textit{xillvercp} and \textit{relxillcp}. In P1 the inner radius is found consistent with being constant among the pointings, similar to the ionization parameter \( \xi \), which best-fitting values are found to be \( R_{in} \approx 40 \ r_g \) and \( \log \xi \gtrsim 3 \) \([\text{log (erg cm s}^{-1})]\). While fitting, we let free to vary but tied between the observations both \( R_{in} \) and \( \log \xi \).
show the Comptonizing and the reflection components in Fig. 4. The primary $kT_{hc}$ is tied to the same parameter of the $nthcomp$ component used for reproducing the soft-excess.

Then, we end up with the following model:

$$\text{redden} \times \text{phabs} \times \text{const} \times n \text{atable(WA1)} \times n \text{atable(WA2)} \times \times [\text{gauss} + n \text{atable(small BB)} + nthcomp_{wc} + n \text{atable(REFL)} + +xillvercp + nthcomp_{hc} + rexlilcp].$$

The adoption of this model results in a best fit of $\chi^2 = 2357$ for 2189 d.o.f., see Fig. 5. The values of the best-fitting parameters are reported in Table 2. A super Solar iron abundance $A_{Fe} = 2.8^{+0.2}_{-0.3}$ is required by the fit, and this value is in agreement with the abundance quoted in P1 ($A_{Fe} = 2.6^{+0.3}_{-0.2}$). The disc temperature is found to be constant among the pointings with a corresponding best-fitting value of $kT_{bb} = 12 \pm 1$ eV. As in P1, the hard component displays variability since $\Gamma_{hc}$ ranges between 1.71 and 1.85, and a similar behaviour is found for the $nthcomp$ modelling the soft-excess ($\Delta \Gamma_{wc} \sim 0.3$), see Figs 6 and 7. The electron temperature $kT_{hc}$ remains unconstrained in most of the observations, apart from observation 2, where the fit returns $kT_{hc} = 17^{+20}_{-10}$ keV. However, from Fig. 7, hints of variability for the physical properties of the hot corona remain. On the other hand, the warm corona temperature is consistent with being constant: $kT_{wc} = 0.12 \pm 0.01$ keV. We then use the best-fitting values of the hot corona and warm corona temperature to calculate the corresponding optical depths of the electron distributions. To do this, we take advantage of the $nthcomp$ internal routine used to compute the Thomson optical depth. This procedure assumes a spherical plasma geometry. For both the Comptonizing components the best-fitting values for the optical depths are reported in Table 2. The optical depth of the hot component can be constrained only for observation 2, $\tau_{hc} = 2.1^{+0.4}_{-0.9}$, and, for the remaining observations, upper limits are found to be in the range $0.9 \leq \tau_{hc} \leq 3.2$ The optical depth of the warm component is found to vary. The $\tau_{wc}$ ranges between $\sim 35$ and $\sim 50$.

Finally, we searched for correlations between the best-fitting parameters quoted in Table 2. The Pearson cross-correlation coefficients ($P_{cc}$) and the corresponding null probability $P(r > \cdot \cdot \cdot)$ are shown in Table 3. Strong anticorrelations are found between the coronal temperature and the optical depth for both the hot and warm components. A noticeable anticorrelation occur also between $\Gamma_{hc}$ ($\Gamma_{wc}$) and $\tau_{hc}$ ($\tau_{wc}$), and, interestingly, the photon index of these two components are significantly anticorrelated. In fact, as shown in Fig. 8, lower $\Gamma_{hc}$ values correspond to steeper $\Gamma_{wc}$. The Pearson cross-correlation coefficient is $P_{cc} = -0.82$ with a corresponding null probability of 0.03. We have further tested this latter correlation checking for dependencies or degeneracies due to the model. Contours in Fig. 8 show that the correlation is not due to model parameter degeneracy. Moreover, we checked for the presence of additional degeneracies between the parameters, in particular focusing on the hard Comptonizing component and the reflection one. However, the computed contours are flat, thus no degeneracy is present between the parameters of interest, see Fig. 9.

### 4 DISCUSSION

We have performed a multiwavelength spectral investigation on the high-S/N data of five simultaneous XMM–Newton and NuSTAR observations of NGC 4593. As commonly observed in Seyfert galaxies (e.g. Piconcelli et al. 2005; Bianchi et al. 2009; Scott, Stewart & Mateos 2012), the broad-band emission of NGC 4593 displays the presence of two main components, a primary power law and a soft-excess that becomes prominent below $\sim 1$ keV (see P1).
Both components show strong variability (see fig. 1 of P1). Flux variations are typical of AGN activity, and in the X-rays, they are observed down to time-scales of hours. On such short time-scales, variability can be used to probe the innermost regions of AGN. Several authors showed that this variability is correlated with the black hole (BH) mass (e.g. Nandra et al. 1997; Czerny et al. 2001; Vaughan et al. 2003; Nikolajuk, Papadakis & Czerny 2004; McHardy et al. 2006). We then follow Ponti et al. (2012) to compute the normalized excess variance and its associated error for NGC 4593 obtaining $\sigma_{\text{rms}} = 0.03 \pm 0.002$ in the 2–10 keV band. Adopting the relation between $\sigma_{\text{rms}}$ and $M_{\text{BH}}$, we estimate the NGC 4593 BH mass to be $M_{\text{BH}} = (5.8 \pm 2.1) \times 10^5 M_\odot$. Our estimate is marginally compatible with the reverberation mapping value provided by Denney et al. (2006): $M_{\text{BH}} = (9.8 \pm 2.1) \times 10^5 M_\odot$.

Moreover, in this study we show that the optical-UV/X-rays emission of NGC 4593 can be explained in terms of two Comptonization components, a warm optically thick corona, and a hot optically thin medium. The soft-component photon index shows significant variations between the different observations ($2.35 \leq \Gamma_{\text{wc}} \leq 2.74$, see Fig. 6), while the corresponding electron temperature displays a more constant behaviour (on average $kT_{\text{wc}} = 0.12 \pm 0.01$ keV). Therefore, the observed variability has to depend on $\tau_{\text{wc}}$, which we estimate to vary in the range $35 < \tau_{\text{wc}} < 47$. On the other hand, also the hot component displays remarkable spectral variations (see Fig. 6), with variability found for both the hot electron temperature and $\tau_{\text{hc}}$.

For the hot corona, $kT_{\text{hc}}$ and $\tau_{\text{hc}}$ seem to be anticorrelated and their trend is in agreement with that reported by Tortosa et al. (2018). However, our result is not very significant since it is only based on lower (upper) limits for $kT_{\text{hc}}$ ($\tau_{\text{hc}}$).

### 4.1 Warm and hot corona regions in NGC 4593

From the best-fitting model we can compute the total flux emitted by the warm and hot corona ($F_{\text{tot};\text{soft(hard)}}$), as well as the seed soft photon flux entering them and cooling them ($F_{\text{soft(hard)}}$), see Table 4. With the estimate of the coronal best-fitting optical depth we can deduce the so-called Compton amplification factor $A$ (see Petrucci et al. 2018, for details). This factor accounts for the ratio between the total power emitted by the warm corona and the seed soft luminosity from the accretion disc, and it can be used to estimate the geometrical properties of the Comptonizing medium. In particular, following the steps described by Petrucci et al. (2018) we find that the amplification factor for the warm corona $A_{\text{wc}}$ ranges between 1.6 and 2. An amplification $A_{\text{wc}} \approx 2$ is theoretically expected for an optically thick and slab corona fully covering a passive disc (e.g. Petrucci et al. 2013), thus this is in agreement with a scenario in which the soft-excess arises from a warm and optically thick medium being the upper layer of a nearly passive accretion disc (Różańska et al. 2015). Again, following the procedure in Petrucci et al. (2018), we also estimate the amplification factor corresponding to the hot component, $A_{\text{hc}}$. In this case, the electron temperature is poorly constrained, and we estimate lower limits for this parameter. These lower limits translate to upper limits for the amplification factor of the hard corona $A_{\text{hc}}$ found to be in the range 50–100. Following equations (18) and (23) in Petrucci et al. (2018), these translate to lower limits of the patchiness factor of the hard corona which is of the order of $2/A_{\text{hc}}$ for an optically thin corona above a passive disc (i.e. with no intrinsic emission Petrucci et al. 2013). We obtain $g > 0.02$. These values are in agreement with a scenario in which an extended Thomson thick medium is responsible for the optical-UV/soft X-ray of NGC 4593, while a
Table 3. The Pearson cross-correlation coefficients and their corresponding null hypothesis probabilities are reported for all the best-fitting values of the parameters quoted in Table 2. The X is used when the two parameters of interest are not significantly correlated ($P_{\text{cc}} < 0.70$).

Figure 4. The Comptonizing and reflection components are displayed. In orange and cyan the warm and hot corona contribution while components in green and purple account for distant and relativistic reflection, respectively. For the sake of simplicity we do not report the different absorbing components. Example of the Comptonizing and reflection components from the best fits of Obs 1b.

Concerning the interplay between the warm and hot coronal emission, in Fig. 10 we show that the primary X-ray flux is tightly correlated with the flux of the soft-excess component. The Pearson correlation coefficient of $P_{\text{cc}} = 0.95 (P(\text{cc}) = 0.02)$ suggests that the soft-excess increases for an increasing primary flux. Moreover, the photon indices of both the Comptonization components are correlated with the 2-10 keV component flux, see Fig. 11.

The tight correlation we find between the photon index of the hot and warm corona is quite unusual and difficult to explain. Concerning the evolution of the hot corona properties ($\Gamma_{\text{hc}}$ and flux), it is interesting to note that the softer and more luminous spectra roughly correspond to the observations with the highest UV flux. This is not a strong effect given the small variability of the UV flux, but it suggests a simple interpretation. Qualitatively, the spectral and luminosity change can be explained assuming that the outer disc/warm corona structure pushes a bit closer to the black hole (the transition radius $R_t$ between the hot and the warm corona decreases), decreasing the portion of the hot corona which ‘sees’ an increase of the UV-EUV soft radiation. This would cause a more effective cooling of the hot gas explaining the softening of the spectrum. If this interpretation is correct however, we would expect then...
a decrease in the hot corona temperature. This is in contradiction with the lowest value of the temperature, observed during observation 2, while the UV flux is also the lowest. Moreover, it is not easy to understand why, in these conditions, the warm corona photon index would evolve in an opposite way.

Actually the anticorrelation of $\Gamma_{hc}$ and $\Gamma_{wc}$ could be a by-product of the radiative coupling between the two coronae. We have reported in Table 5 the correlation coefficient between the total corona flux, the seed soft photon flux and the photon index of both coronae. Interestingly, $F_{\text{tot-soft}}$ strongly correlates with $F_{\text{hard}}$ ($P_{cc} = 0.83$). This correlation agrees with the warm corona acting as the seed photon source for the hot corona. The larger $F_{\text{tot-soft}}$ the larger $F_{\text{hard}}$ but, at the same time, the steeper the hot corona spectrum due to the increase of the cooling ($\Gamma_{hc}$ increases as indeed observed). On the other hand, $\Gamma_{wc}$ anticorrelates quite strongly with $F_{\text{hard}}$ (the correlation is even stronger than between $\Gamma_{wc}$ and $\Gamma_{hc}$).

Figure 5. The broad-band best fit corresponding to $\chi^2 = 2357$ for 2189 d.o.f. is shown for all the observations in the top part of the graphs while the residuals with respect to the errors are displayed in the bottom sub-panels.
Figure 6. The warm and hot Comptonizing components for the various observations.

Figure 7. Confidence regions at 90 per cent confidence level for the photon index and hot corona temperature (top panel), and for the warm corona.

Figure 8. Top panel: The photon index for the hot corona and warm corona are reported. The solid line represent the fit to the points and the associated Pearson coefficient and null probability are also shown. Bottom panel: Contours at 90 per cent confidence level of both $\Gamma_{hc}$ and $\Gamma_{wc}$ for each observation. Flat contours indicate that the two interesting quantities are measure independently, therefore the correlation is not due to the presence of degeneracy.

Possibly there is some feedback then in the sense that when $F_{\text{tot-soft}}$ increases also $F_{\text{tot-hard}}$ increases. Then, the heat deposit in the warm corona by e.g. illumination increases (indeed, $F_{\text{tot-hard}}$ correlates with $F_{\text{rel-refl}}$), producing a hardening ($\Gamma_{wc}$ decreases) of the warm corona spectrum.

The main problem with this interpretation is the evolution of the coronal temperature. We would expect the temperature to decrease/increase when the spectrum steepens/hardens. These observations do not show clear evolution of these temperatures. This suggests that something else may have to change, e.g. the optical depth, to keep the temperature roughly constant.

Note that we have assumed a constancy of the warm corona geometry. Its variation is however plausible and should add another free parameter to explain the observations. Indeed, variability of the optical-UV-to-X-rays emission of NGC 4593 could result from...
Testing the two-corona model on NGC 4593

Figure 9. Contours at 90 per cent confidence level for the reflection fraction and the hot corona temperature (top panel). Contours are flat, thus no degeneracy is present between the parameters.

Table 4. We report in this table the best-fitting fluxes entering ($F_{\text{soft}}$ and $F_{\text{hard}}$) and emitted ($F_{\text{tot-soft}}$ and $F_{\text{tot-hard}}$) by the soft and hard corona. Moreover, the flux due to relativistic reflection is also reported. All fluxes $F_{\text{tot-soft}}$, $F_{\text{tot-hard}}$, $F_{\text{soft}}$, $F_{\text{hard}}$, and $F_{\text{rel-refl}}$ are in units of $10^{-11}$ erg cm$^{-2}$ s$^{-1}$, and are computed in the 0.001–1000 keV energy interval.

|          | Obs. 1a | Obs. 1b | Obs. 2 | Obs. 3 | Obs. 4 | Obs. 5 |
|----------|---------|---------|--------|--------|--------|--------|
| $F_{\text{soft}}$ | 9.2     | 9.2     | 6.9    | 8.9    | 13.4   | 14.6   |
| $F_{\text{hard}}$ | 1.0     | 0.5     | 0.3    | 0.3    | 0.9    | 1.0    |
| $F_{\text{rel-refl}}$ | 1.8     | 1.3     | 0.8    | 1.3    | 2.7    | 2.1    |
| $F_{\text{tot-soft}}$ | 17.8    | 15.2    | 11.3   | 14.3   | 23.6   | 25.6   |

Figure 10. The primary X-ray flux (2–10 keV) of the hot nthcomp component versus the flux (0.3–2 keV) of the warm nthcomp component, as measured in the different observations. The linear fit to the data is displayed by the solid black line ($P_{cc} = 0.88$ ($P(\gamma>\gamma) = 0.03$) and $P_{cc} = -0.88$ ($P(\gamma>\gamma) = 0.03$) for the $\Gamma_{hc}$ and $\Gamma_{wc}$, respectively.

Figure 11. The photon index of the hot and warm corona are shown as a function of the 2–10 keV hot component flux. The photon index for both the components are found correlated with the 2–10 keV flux with corresponding Pearson coefficients $P_{cc} = 0.88$ ($P(\gamma>\gamma) = 0.03$) and $P_{cc} = -0.88$ ($P(\gamma>\gamma) = 0.03$) for the $\Gamma_{hc}$ and $\Gamma_{wc}$, respectively.

geometrical variations of the ‘two coronae’ but also of the ‘warm corona’ and outer part of the disc, not covered by the warm corona, and, potentially, also contributing to the optical-UV emission. A detailed analysis of the parameter space, also adopting more sophisticated models (e.g. agnsed Kubota & Done 2018) self-consistently accounting for the disc contribution in the frame-work of two Comptonizing coronae, is however out of the scope of this paper and is deferred to a future work.
4 The two-corona model in the best monitored Seyfert galaxies

Simultaneous observations including optical-UV and X-ray information have been crucial in testing the two-corona model on AGN. XMM–Newton–NuSTAR monitorings have been performed on a handful of local Seyfert galaxies, for instance NGC 7469 (Behar et al. 2017) and 3C 382 (Ursini et al. 2018). The two-corona model was already tested on these AGN (Middei et al. 2018; Ursini et al. 2018), and they were objects of multi-epoch campaigns analogously to NGC 4593. NGC 7469 is a type 1 Seyfert galaxy characterized by a SMBH mass of (1.1 ± 0.1) × 10^9 M⊙ (Peterson et al. 2014), while a BH mass of (1.0 ± 0.3) × 10^9 M⊙ is found for the broad-line radio galaxy 3C 382 (Fausnaugh et al. 2017), about 2 orders of magnitude larger than NGC 4593. The comparison of these results with those of NGC 4569 and 3C 382 emphasizes the NGC 4593 peculiar behaviour. First, phenomenologically, the emission of NGC 4593 is characterized by strong variability, both in flux and spectral shape, and its high-energy cut-off is found to vary (also see P1). These behaviours were not observed, at least during the monitorings, in NGC 7469 or 3C 382. In fact, the hard X-ray emission of NGC 7469 was consistent with a constant photon index (Γ_NGC 7469 = 1.78 ± 0.02) between the different pointings, and a non-variable high-energy cut-off was measured to be E_NGC 7469 > 170 keV (Middei et al. 2018). In a similar fashion, 3C 382 also can be described in terms of a constant photon index (Γ_3C 382 = 1.78 ± 0.01). Furthermore, the physical properties of the hot Comptonizing component acting in NGC 4593 are found to vary (κ_{hc} and τ_{hc}), while these quantities in both NGC 7469 and 3C 382 displayed a more constant behaviour with corresponding electron temperature of kT_{hc,NGC 7469} = 45 ± 15 keV and kT_{hc,3C 382} > 20 keV, respectively.

On the other hand, the properties of the soft-excess are more similar among these AGN. In fact, NGC 4593, 3C 382, and NGC 7469 all display a soft-excess that cannot be explained in terms of ionized reflection alone (P1, Ursini et al. 2018; Middei et al. 2018), while a warm Comptonization scenario characterized by a variable photon index and a constant electron temperature is favoured. Indeed, the kT_{wc} of NGC 4593, NGC 7469, and 3C 382 (~0.12 keV, ~0.7 keV, and ~0.6 keV, respectively) are consistent with being constant during the monitorings. Remarkable Γ_{wc} variability is found in NGC 4593, noticeable variations are observed in the warm photon index of 3C 382 and weaker variability in the Γ_{wc} of NGC 7469 are measured. Moreover, the anticorrelation between the photon index of the two Comptonizing component is not found in NGC 7469 and 3C 382, making NGC 4593 peculiar in this respect.

5 SUMMARY

This paper is the second article reporting on the observational campaign targeting NGC 4593. In particular we tested the two-corona model (e.g. Petrucci et al. 2013; Rózańska et al. 2015) on this rich high-S/N data set. The obtained overall scenario is consistent with the two-corona model in which two Comptonization processes dominate the soft and hard X-ray emission of the source. We report our findings and conclusions in the following:

(i.) Strong flux variability is observed during the monitoring and variations are observed from daily down to hourly time-scales. We adopted the normalized excess variance to quantify the source variability finding σ^2_{rms} = 0.003 ± 0.002 in the 2–10 keV band. Following Ponti et al. (2012), we convert this value into an estimate of the BH mass hosted by NGC 4593, obtaining M_{BH} = (5.8 ± 2.1) × 10^6 M⊙. This value is marginally in agreement with the reverberation mapping measure by Denney et al. (2006).

(ii.) A hot Comptonization component describes the high-energy spectra of our campaign. This hot corona is phenomenologically described by a variable photon index (1.71 ≤ Γ_{hc} ≤ 1.85). The hot corona temperature remains unconstrained in five over six observations. On the other hand, hints of variability are found for this parameter and this is in agreement with the high-energy-cut-off variability reported in P1. In turn, we find upper limits for the optical depth of the hot corona. We notice that κ_{hc} and τ_{hc} anticorrelate (P_{ anticorrelation} = 0.85 P(r > 4 per cent).

(iii.) All spectra display a remarkable soft-excess, and a warm Comptonization model best describes this component. The warm medium is characterized by a variable photon index 2.35 < Γ_{wc} < 2.74 and a constant kT_{wc} = 0.12 ± 0.01 keV. The optical depth of the warm corona is variable 35 ≤ τ_{wc} ≤ 47. According to this analysis, most of the accretion power is released in the warm-corona than in the accretion disc.

(iv.) For the first time, we observe an anticorrelation between the photon indexes of the hot and the warm corona. The origin of this trend cannot be ascribed to a model degeneracy (see Fig. 8). The interpretation of such anticorrelation is not straightforward but can result from the radiative feedback between the two coronae.

(v.) This test on the two-corona model indicates that it reliably allows for reproducing the AGN broad-band emission. Indeed, besides observational differences with other sources that can be explained in terms of different physical properties (e.g. Eddington ratio), notably the two-corona model provides good representations of the data suggesting that it accounts for a common Comptonizing mechanism occurring in AGN. On the other hand, the existence of a warm corona at such temperature and optical depth above the accretion disc is expected to produce emission/absorption features from the ionized matter. The fact that we do not see any of them
ACKNOWLEDGEMENTS
