Abstract. We introduce a transport approach at fixed shear viscosity to entropy ratio $\eta/s$ to study the generation of collective flows in ultra-relativistic heavy-ion collisions. Transport theory supplies a covariant approach valid also at large $\eta/s$ and at intermediate transverse momentum $p_T$, where deviations from equilibrium is no longer negligible. Such an approach shows that at RHIC energies a temperature dependent $\eta/s$ enhances significantly the $v_2/v_2^2$ respect to the case of constant $\eta/s$. Furthermore if NJL chiral dynamics is self-consistently implemented we show that it does not modify the relation between $v_2$ and $\eta/s$.

1. Introduction

The RHIC program at BNL has shown that the azimuthal asymmetry in momentum space, namely the elliptic flow $v_2$, is the largest ever seen in HIC suggesting that an almost perfect fluid with a very small shear viscosity to entropy density ratio, $\eta/s$, has been created [1, 2]. Nonetheless it has been found that dissipative effects cannot be neglected and even a small shear viscosity to entropy ratio $\eta/s$ produce sizeable effect increasing with the transverse momentum $p_T$, where deviations from equilibrium is no longer negligible. This has triggered a lot of activity in developing a relativistic theory of viscous hydrodynamics. Viscous corrections to ideal hydrodynamics are indeed large and a simple relativistic extension of first order Navier Stokes equations is affected by causality and stability pathologies [5]. It is therefore necessary to go to second order gradient expansion, and in particular the Israel-Stewart theory has been implemented to simulate the RHIC collisions providing an upper bound for $\eta/s \leq 0.4$ [4]. Such an approach, apart from the limitation to 2+1D simulations, has the more fundamental problem of a limited range of validity in $\eta/s$ and in the transverse momentum $p_T$.

On the contrary a relativistic transport approach has the advantage to be a 3+1D approach not based on a gradient expansion in viscosity that is valid also for large $\eta/s$ and for out of equilibrium momentum distribution allowing a reliable description also of the intermediate $p_T$ range where the important property of quark number scaling (QNS) of $v_2(p_T)$ has been observed [10]. In this $p_T$ region viscous hydrodynamics breaks its validity because the relative deviation of the equilibrium distribution function $\delta f/f_{eq}$ increases with $p_T^2$ becoming large already at $p_T \geq 3T \sim 1\text{GeV}$ [4]. Furthermore Boltzmann-Vlasov transport theory distinguishes between the short range interaction associated to collisions and long range interaction associated to the field interaction, responsible for the change of the Equation of State (EoS) respect to that of a free gas. This last feature allows to unify two main ingredients that are relevant for the formation of collective flow. In ideal hydrodynamics the $v_2(p_T)$ depends strongly on the EoS namely on...
the sound velocity $c_s^2 = dP/de$ [8], while the mean free path $\lambda$ is assumed to be vanishing. In the parton cascade approach the EoS is fixed to be the one of a free gas $c_s^2 = 1/3 = P/\epsilon$, on the other hand the mean free path $\lambda = 1/\rho \sigma$ is finite. In the first stage of RHIC the two different approaches were able to account for the large $v_2(p_T)$ observed; in particular the parton cascade with large scattering cross section predicted the saturation of $v_2(p_T)$ vs $p_T$ [9]. Anyway at finite viscosity both $\lambda$ and the EoS are important for the generation of the momentum anisotropies.

The basic equation of transport for the (anti-) quark phase-space distribution function $f^{\pm}$ under a scalar field interaction can be written as:

$$p^\mu \partial_\mu f^\pm(x,p) + M(x) \partial_\mu M(x) \partial^\mu f^\pm(x,p) = C(x,p)$$

(1)

where the first term is related to the free streaming, the second term represents the effect of a scalar field modifying the $\epsilon = 3P$ relation (giving a finite interaction measure, see Fig.2 (left)) and the last term describes the collision dynamics associated to a finite $\lambda$, hence a finite $\eta/s$.

In the following we will show two results obtained with such an approach: one related with the large $v_4/v_2^2$ ratio observed at RHIC and the other discussing the role of the NJL chiral dynamics on the relation between $v_2(p_T)$ and $\eta/s$. We will show calculations for $Au + Au$ at 200 AGeV; the density distribution in coordinate space is given by the standard Glauber model. The maximum initial temperature is $T = 340$ MeV and the initial time is $\tau_0 = 0.6$ fm/c as usually done also in hydrodynamical calculations.

2. The large $v_4/v_2^2$ ratio

We first consider the reduction of the transport approach to a cascade, i.e. neglect the field interaction, included in the next section. In such a case the mass $M(x) = 0$ in Eq.(1). It has been shown that a fluid at finite $\eta/s$ can be studied within a transport approach renormalizing locally the scattering cross section according to $\eta/s = \sigma_T = <p> / 15 \rho$, for details see Refs [6, 7, 5]. The system of course expands and cools and when the energy density is below $\epsilon \sim 2 GeV/fm^3$ it starts the cross-over region and then the hadronic stage. During this phase we increase the $\eta/s$ of the medium according to Fig. 1 (left) in order to have finally in the hadronic phase an $\eta/s = 8/4\pi \sim 0.65$ in agreement with several calculation of $\eta/s$.

At RHIC it has been observed $v_4(p_T)/v_2^2(p_T)$ ratio of about 0.8-0.9 [11] quite larger than first ideal hydrodynamical predictions of about 0.5. More realistic hydrodynamical calculations show that the ratio can be even lower than 0.5 and viscosity does not strongly affect such a ratio but can bring it up to about 0.6. Furthermore in Ref.[12] it has been shown that such a ratio is almost independent on the initial eccentricity, on the viscosity, on the particle species. Therefore even if $v_4$ and $v_2$ can depend on several details such a ratio is a quite stable one and its large value should be considered as an opportunity to have some new information on the system not yet spot. In Ref.[7] we have shown that indeed the formation time of $v_4$ is larger than the $v_2$ one and therefore it is more affected by dynamics of the later stage of the reaction. Thanks to the difference in the formation time we argue that such a ratio is significantly affected by the temperature dependence of the $\eta/s$. Therefore we have performed two calculations one with a constant $4\pi \eta/s = 1$ in the QGP phase (dashed line) and the other, shown by solid line in Fig. 1 (left), with a $T$ or $\epsilon$ energy density dependence $4\pi \eta/s = T/T_0 = (\epsilon/\epsilon_0)^{1/4}$ where $\epsilon_0 = 1.7 GeV/fm^3$ gives the beginning of the cross over region. The plot in Fig. 1 (left) is just a simple sketch of a possible realistic behavior but does not corresponds to any attempted calculations. However we remind that an increase of $\eta/s$ is expected moving away from the phase transition region on general considerations [13].

In Fig.1 (right) we show the results of the two calculations for $Au + Au$ at 200 AGeV. For a constant $\eta/s$ we find a value of about 0.6 while in the case of a temperature dependent $\eta/s$, it increases getting very close to experimental data, $v_4/v_2^2 \sim 0.8$. The reason for the sensitivity of this ratio on the $T$ dependence is that the elliptic flow $v_2$ mainly develops earlier respect to $v_4$.
and therefore on the average at larger \( \eta/s \) (for the solid line case), while \( v_4 \) develops more when the \( \eta/s \) is smaller hence is less suppressed by dissipative effects.

### 3. Impact of NJL Dynamics

To start the investigation of the role of the field interaction we have implemented the NJL dynamics that introduces the generation of a finite mass associated to chiral symmetry breaking. Therefore particles do not have a vanishing mass but a finite one according to the mass gap equation of the NJL model:

\[
\frac{M(x) - m}{4 g N_c} = M(x) \int \frac{d^3p}{(2\pi)^3} \frac{1 - f^-(x,p) - f^+(x,p)}{E_p(x)}
\]

that determines the local mass \( M(x) \) at the space-time point \( x \) in terms of the distribution functions \( f^\pm(x,p) \). For a gas at finite mass \( \epsilon - 3P \) is no longer vanishing as shown in Fig.2 (left) for several NJL parametrization.

Eqs.(1) and (2) form a closed system of equations constituting the Boltzmann-Vlasov equation associated to the NJL Lagrangian. The space-time dependence of the mass \( M_s(r,t) = m - 2g \langle \bar{\psi} \psi \rangle \) influences the momenta of the particles because the finite gradient of the condensate generates a force which changes the momentum of a particle proportionally to \( \vec{\nabla}_r (\bar{\psi} \psi) \). The last is negative because the phase transition occurs earlier in the surface of the expanding QGP fireball. Therefore the phase transition which takes place locally results in a negative contribution to the particle momenta that makes the system more sticky respect to a free massless gas. To study a fluid at finite \( \eta/s \) and NJL field interaction one has to extend the simple relation \( \sigma_{tr} \cdot \eta/s = < p > /15\rho \) valid for a massless gas to the general case of massive relativistic particles and this has been discussed in Ref.[14].

In Fig.2, we show the elliptic flow as a function of \( p_T \). We find that the presence of an NJL-field that drives the chiral phase transition suppress the \( v_2(p_T) \) by about 20% at \( p_T > 1 \) GeV. This would imply the need of a parton scattering cross section \( \sigma_{tr} \) even larger than that estimated with the cascade model which was already quite larger than the pQCD estimates [9] in order to describe the data. On the other hand the mean field modifies both the local entropy density, reduced by the mass generation, and the shear viscosity that increases respect to the massless case. Considering that one of the main goal is to determine the \( \eta/s \) of the QGP, we
have investigated what is the action of the mean field once the \( \eta/s \) of the system is fixed to be the same with and without the NJL field. This of course implies different values of the cross section in the two cases.

![Diagram](image)

**Figure 2.** Left: Interaction measure shown as a function of temperature \( T \) for three different NJL parameter sets. Right: Average elliptic flow as a function of time for \( Au+Au \) collisions in the mid-rapidity region \( |y| < 1 \) at \( b=7 \) fm; see text.

The results for \( 4\pi \eta/s = 1 \) are shown by dashed lines in Fig. 2 (right), the (black) dashed line is the case with only the collision term (cascade) while the (green) dashed line is the case with the field. We can see that once the \( \eta/s \) is fixed there is essentially no difference in the calculations with and without a field dynamics included. This is a key result that shows that even in a microscopic approach that distinguishes between the mean field and the collisional dynamics the \( v_2(p_T) \) is mainly driven by the \( \eta/s \) of the fluid. In other words we have found that in a microscopic approach the \( \eta/s \) is the pertinent parameter and the language of viscous hydrodynamics is appropriate. Of course this does not mean that \( v_2(p_T) \) in the transport theory is the same as in viscous hydrodynamics (especially at \( p_T > 1.5 \) GeV), but that the direct relation between \( v_2(p_T) \) and \( \eta/s \) is not modified by the NJL field dynamics. This confirms the validity of the studies pursued till now even if they miss an explicit mean field or chiral dynamics.
