Abstract Looking at a person’s hands one often can tell what the person is going to do next, how his/her hands are moving and where they will be, because an actor’s intentions shape his/her movement kinematics during action execution. Similarly, active systems with real-time constraints must not simply rely on passive video-segment classification, but they have to continuously update their estimates and predict future actions. In this paper, we study the prediction of dexterous actions. We recorded from subjects performing different manipulation actions on the same object, such as “squeezing”, “flipping”, “washing”, “wiping” and “scratching” with a sponge. In psychophysical experiments, we evaluated human observers’ skills in predicting actions from video sequences of different length, depicting the hand movement in the preparation and execution of actions before and after contact with the object. We then developed a recurrent neural network based method for action prediction using as input patches around the hand. We also used the same formalism to predict the forces on the finger tips using for training synchronized video and force data streams. Evaluations on two new datasets show that our system closely matches human performance in the recognition task, and demonstrate the ability of our algorithms to predict real-time what and how a dexterous action is performed.

1 Introduction

Human action and activity understanding has been a topic of great interest in Computer Vision and Robotics in recent years. Many techniques have been developed for recognizing actions and large benchmark datasets have been proposed, with most of them focusing on full-body actions (Mandary et al. 2015; Takano et al. 2015; Schuldt et al. 2004; Li et al. 2010; Moeslund et al. 2006; Turaga et al. 2008). Typically, computational approaches treat action recognition as a classification problem, where the input is a previously segmented video, and the output a set of candidate action labels.

However, there is more to action understanding, as demonstrated by biological vision. As we humans observe, we constantly perceive, and update our belief about the observed action and about future events. We constantly recognize the ongoing action. But there is even more to it. We can understand the kinematics of the ongoing action, the limbs’ future positions and velocities. We also understand the observed actions in terms of our own motor-representations. That is, we are able to interpret others’ actions in terms of dynamics and forces, and predict the effects of these forces on objects. Similarly, cognitive robots that will assist human partners will need to understand their intended actions at an early stage. If a robot needs to act, it cannot have a long delay in visual processing. It needs to recognize in real-time to plan its actions. A fully functional perception action loop requires the robot to predict, so it can efficiently allocate future processes. Finally, even vision processes for multimedia tasks may benefit from being predictive. Interpreting human activities is a very complex task and requires both, low-level vision processes and high-level cognitive processes with knowledge about actions. (Gupta and Davis 2008; Kulkarni et al. 2013). Considering the challenges in state of the art visual action recognition, we argue that by integrating closely the
high-level with the low-level vision processes, with the high-level modifying the visual processes (Aloimonos and Fermüller, 2015). A better recognition may be achieved. Prediction plays an essential component in this interaction. We can think about the action-perception loop of our cognitive system from the viewpoint of a control system. The sensors take measurements of the human activity. We then apply visual operations on this signal and extract (possibly using additional cognitive processes) useful information for creating the control signal in order to change the state of the cognitive system. Because the processing of the signal takes time, this creates a delay for the control (Doyle and Csete, 2011). It is therefore important to compute meaningful information that allows us to predict the future state of the cognitive system. In this work, we are specifically interested in manipulation actions and how visual information of hand movements can be exploited for predicting future action so that the crucial delay in the control loop can be shortened (for an illustration see Fig. 1).

Hand movements and actions have long been studied in Computer Vision to create systems for applications such as recognition of sign language (Erol et al, 2007). More recent applications include gesture recognition (Molchanov et al, 2015), visual interfaces (Melax et al, 2013), and driver analysis (Ohn-Bar and Trivedi, 2014). Different methods model the temporal evolution of actions using formalisms such as Hidden Markov models (Starner et al, 1998), Conditional Random Fields (Wang et al, 2006) and 3d Convolutional Neural Networks (Molchanov et al, 2015). While in principle, some of these approaches, could be used for online prediction, they are always treated as recognition modules. In recent years a number of works have developed tools for general hand pose estimation and hand tracking, which can be building blocks for applications involving hand movement recognition. For example, building on work on full-body recognition (Shotton et al, 2013), (Keskin et al, 2013) develops a learning-based approach using depth contrast features and Random Forest classifiers, Oikonomidis et al (2011) in a model-based approach use a 27-degree of freedom model of the hand built from geometric primitives and GPU accelerated Particle Swarm Optimization. So far, these trackers and pose estimators work well on isolated hands, but methods still struggle with hands in interaction with objects (Supancic et al, 2015), although there are efforts underway to deal with such situations (Panteleris et al, 2015).

Inspiration for our work comes from studies in Cognitive Sciences on hand motion. The grasp and the movement kinematics are strongly related to the manipulation action (Jeannerod, 1984). It has been shown that an actor’s intention shapes his/her movement kinematics during movement execution, and, furthermore, observers are sensitive to this information (Ansuini et al, 2015). They can see early differences in visual kinematics and use them to discriminate between movements performed with different intentions. Kinematic studies have looked at such physical differences in movement. For example, Ansuini et al (2008) found that when subjects grasped a bottle for pouring, the middle and the ring fingers were more extended than when they grasped the bottle with the intent of displacing, throwing, or passing it. Similarly, Crajé et al (2011) found that subjects placed their thumb and index fingers in higher positions when the bottle was grasped to pour than to lift.

It appears that the visual information in the early phases of the action is often sufficient for observers to understand the intention of action. Starting from this intuition, we a.) conducted a study to evaluate humans’ performance in recognizing manipulation actions; b.) implemented a computational system using state-of-the-art learning algorithms.

The psychophysical experiment was designed to evaluate human’s performance in recognizing manipulation actions in their early phases. These include: 1) the grasp preparation, which is the phase when the hand moves towards the object and the fingers shape to touch the object; 2) the grasp, when the hand comes in contact with the object to hold it in a stable position; and 3) the early actual action movement of the hand together with the object. Throughout these three phases, observers’ judgment of the action becomes more reliable and confident. The study gives us an insight about the difficulty of the task and provides data for evaluating our computational method.

Our computational approach processes the sensory input as a continuous signal and formulates action interpretation as a continuous updating of the prediction of intended action. This concept is applied to two different tasks. First, from the stream of video input, we continuously predict the identity of the ongoing action. Second, using as input the
video stream, we predict the forces on the fingers applied to grasped objects. Next, we provide a motivation for our choice of the two tasks, after which we give an overview of our approach.

The first task is about action prediction from video. We humans are able to update our beliefs about the observed action, and predict it before it is completed. This capability is essential to be pro-active and react to the actions of others. Robots that interact with humans also need such capability. Predicting future actions of their counterpart allows them to allocate computational resources for their own action appropriately. For example, if a person is passing a cup to the robot, it has to understand what is happening well before the action is completed, so it can prepare the appropriate action to receive it. Furthermore, vision processes have to be initiated and possibly tuned with predicted information, so the cup can be detected at the correct location, its pose estimated, and possibly other task-specific processes performed (for example, the content of the cup may need to be recognized).

The second task is about predicting the tactile signal of the intended action. Findings of neuroscience on the mirror neuron system (Gallese and Goldman 1998, Rizzolatti et al. 2001) provide evidence for a close relationship between mechanisms of action and perception in primates. Humans develop haptic perception through interaction with objects and learn to relate haptic with visual perception. Furthermore, they develop the capability of hallucinating the haptic stimulus when seeing hands in certain configurations interacting with objects (Test and Kappers 2014). This capability of hallucinating force patterns from visual input is essential for a more detailed analysis of the interaction with the physical world. It can be used to reason about the current interaction between the hand and the object, and to predict the action consequences driven by the estimated force pattern.

Furthermore, by associating vision with forces, we expect to obtain better computational action recognition modules. Intuitively, the force vectors, whose dimensions are much lower than the visual descriptors, should provide useful compact information for classification, especially when the training data is not large. A first experiment, presented in Section 6.3.3, confirms this idea.

Most important, the force patterns may be used in robot learning. A popular paradigm in Robotics is imitation learning or learning from demonstration (Argall et al. 2009), where the robot learns from examples provided by a demonstrator. If the forces can be predicted from images, then the force profiles together with the positional information can be used to teach the robot with video only. Many researchers are trying to teach robots actions and skills that involve forces, e.g., wiping a kitchen table (Gams et al. 2010), pull and flip tasks (Kober et al. 2009), ironing or opening a door (Kormushev et al. 2011). These approaches rely on haptic devices or force and torque sensors on the robot to obtain the force profiles for the robot to learn the task. If we can predict the forces exerted by the human demonstrator, the demonstration could become vision only. This would allow us to teach robots force interaction tasks much more efficiently.

In order to solve the above two tasks, we take advantage of new developments in machine learning. Specifically, we build on the recent success of recurrent neural networks (RNNs) in conjunction with visual features from pre-trained convolutional neural networks (CNNs) and training from a limited number of weakly annotated data. For the first task, we use an RNN to recognize the ongoing action from video input. A camera records videos of humans performing a number of manipulation actions on different objects. For example, they ‘drink’ from a cup, ‘pour’ from it, ‘pound’, ‘shake’, and ‘move’ it; or they ‘squeeze’ a sponge, ‘flip’ it, ‘wash’, ‘wipe’, and ‘scratch’ with it. Our system extracts patches around the hands, and feeds these patches to an RNN, which was trained offline to predict in real-time the ongoing action. For the second task, we collected videos of actions and synchronized streams of force measurements on the hand, and we used this data to train an RNN to predict the forces, using only the segmented hand patches in video input.

The main contributions of the paper are: 1) we present the first computational study on the prediction of observed dexterous actions 2) we demonstrate an implementation for predicting intended dexterous actions from videos; 3) we present a method for estimating tactile signals from visual input without considering a model of the object; 4) we provide new datasets that serve as test-beds for the aforementioned tasks.

2 Related work

We will focus our review on studies along the following concepts: the idea of prediction, including prediction of intention and future events (a), prediction beyond appearance (b), and prediction of contact forces on hands (c), work on hand actions (d), manipulation datasets (e) and action classification as a continuous process using various kinds of techniques and different kinds of inputs (f).

Prediction of Action Intention and Future Events: A small number of works in Computer Vision have aimed to predict intended action from visual input. For example, Joo et al. (2014) use a ranking SVM to predict the persuasive motivation (or the intention) of the photographer who captured an image. Parsivaal et al. (2014) seek to infer the motivation of the person in the image by mining knowledge stored in a large corpus using natural language processing techniques. Yang et al. (2015) propose that the grasp type, which is recognized in single images using CNNs, reveals
the general category of a person’s intended action. In (Koppula and Saxena 2016), a temporal Conditional Random Field model is used to infer anticipated hand actions by taking into consideration object affordances. Other works attempt to predict events in the future. For example, Kitani et al (2012) use concept detectors to predict future trajectories in a surveillance videos. (Fouhey and Zitnick 2014) learn from sequences of abstract images the relative motion of objects observed in single images. Walker et al (2014) employ visual mid-level elements to learn from videos how to predict possible object trajectories in single images. More recently, Vondrick et al (2016) learn using CNN feature representations how to predict from one frame in the video the actions and objects in a future frame. Our study also is about prediction of future events using neural networks. While the above studies attempt to learn abstract concepts for reasoning in a passive setting, our goal is to perform online prediction of specific actions from video of the recent past.

Physics Beyond Appearance: Many recent approaches in Robotics and Computer Vision aim to infer physical properties beyond appearance models from visual inputs. Xie et al (2013) propose that implicit information, such as functional objects, can be inferred from video. Zhu et al (2015) takes a task-oriented viewpoint and models objects using a simulation engine. The general idea of associating images with forces has previously been used for object manipulation. The technique is called vision-based force measurement, and refers to the estimation of forces according to the observed deformations of an object (Greminger and Nelson 2004). Along this idea, recently Aviles et al (2015) proposed a method using an RNN for the classification of forces due to tissue deformation in robotic assisted surgery.

Inference of Manipulation Forces: The first work in the Computer Vision literature to simulate contact forces during hand-object interactions is Pham et al (2015). Using as input RGB data, a model-based tracker estimates the poses of the hand and a known object, from which then the contact points and the motion trajectory are derived. Next, the minimal contact forces (nominal forces) explaining the kinematic observations are computed from the Newton-Euler dynamics solving a conic optimization. Humans typically apply more than the minimal forces. These additional forces are learned using a neural network on data collected from subjects, where the force sensors are attached to the object. Another approach on contact force simulation is due to Rogez et al (2015). The authors segment the hand from RGBD data in single egocentric views and classify the pose into 71 functional grasp categories as proposed in Liu et al (2014). Classified poses are matched to a library of graphically created hand poses, and theses poses are associated with force vectors normal to the meshes at contact points. Thus the forces on the observed hand are obtained by finding the closest matching synthetic model. Both of these prior approaches derive the forces using model-based approaches. The forces are computed from the contact points, the shape of the hand, and dynamic observations. Furthermore, both use RGBD data, while ours is an end-to-end learning approach using as input only images.

Dexterous Actions: The robotics community has been studying perception and control problems of dexterous actions for decades (Shimoga 1996). Some works have studied grasping taxonomies (Cutkosky 1989; Feix et al 2009), how to recognize grasp types (Rogez et al 2015) and how to encode and represent human hand motion (Romero et al 2013). Pieropan et al (2013) proposed a representation of objects in terms of their interaction with human hands. Real-time visual trackers (Oikonomidis et al 2011) were developed, facilitating computational research with hands. Recently, several learning based systems were reported that infer contact points or how to grasp an object from its appearance (Saxena et al 2008; Lenz et al 2015).

Manipulation Datasets: A number of object manipulation datasets have been created, many of them recorded with wearable cameras providing egocentric views. For example, the Yale grasping dataset (Bullock et al 2015) contains wide-angle head-mounted camera videos recorded from four people during regular activities with images tagged with the hand grasp (of 33 classes). Similarly, the UT Grasp dataset (Cai et al 2015) contains head-mounted camera video of people grasping objects on a table, and was tagged with grasps (of 17 classes). The GTEA set (Fathi et al 2011) has egocentric videos of household activities with the objects annotated. Other datasets have egocentric RGB-D videos. The UCI-EGO (Rogez et al 2014) features object manipulation scenes with annotation of the 3D hand poses, and the GUN-71 (Rogez et al 2015) features subjects grasping objects, where care was taken to have the same amount of data for each of the 71 grasp types. Our datasets, in contrast, are taken from the third-person viewpoint. While having less variation in the visual setting than most of the above datasets, it focuses on the dynamic aspects of different actions, which manipulate the same objects.

Action Recognition as an Online Process: Action recognition has been extensively studied. However, few of the proposed methods treat action recognition as a continuous (in the online sense) process, typically, action classification is performed on whole action sequences (Schuldt et al 2004; Ji et al and Mohan 2014). Recent works include building robust action models based on MoCap data (Wang et al 2014) or using CNNs for large-scale video classification (Karpathy et al 2014; Simonyan and Zisserman 2014a). Most methods that take into account action dynamics usually operate under a stochastic process formulation, e.g., by using Hidden Markov Models (Lv and Nevatia 2006) or semi-Markov models (Shi et al 2011). HMMs can model relations between consecutive image frames, but they cannot be applied
to high-dimensional feature vectors. In (Fanello et al., 2013) the authors propose an online action recognition method by means of SVM classification of sparsely coded features on a sliding temporal window. Most of the above methods assume only short-time dependencies between frames, make restrictive assumptions about the Markovian order of the underlying processes and/or rely on global optimization over the whole sequence.

In recent work a few studies proposed approaches to recognition of partially observed actions under the headings of early event detection or early action recognition. Ryoo (2011) creates a representation that encodes how histograms of spatio-temporal features change over time. In a probabilistic model, the histograms are modeled with Gaussian distributions, and MAP estimation over all subsequences is used to recognize the ongoing activity. A second approach in the paper models the sequential structure in the changing histogram representation, and matches subsequences of the video using dynamic programming. Both approaches were evaluated on full body action sequences. In (Ryoo and Matthias, 2013) images are represented by spatio-temporal features and histograms of optical flow, and a hierarchical structure of video-subsegments is used to detect partial action sequences in first-person videos. Ryoo et al. (2015) perform early recognition of activities in first-person-videos by capturing special sub-sequences characteristic for the onset of the main activity. Hoai and De la Torre (2014) propose a maximum-margin framework (a variant of SVM) to train visual detectors to recognize partial events. The classifier is trained with all the video sub-sequences of different length. To enforce the sequential nature of the events, additional constraints on the score function of the classifier are enforced, for example, it has to increase as more frames are matched. The technique was demonstrated in multiple applications, including detection of facial expressions, hand gestures, and activities.

The main learning tools used here, the RNN and the Long Short Term Memory (LSTM) model, were recently popularized in language processing, and have been used for translating videos to language (Venugopalan et al., 2014), image description generation (Donahue et al., 2015), object recognition (Visin et al., 2014), and the estimation of object motion (Fragkiadaki et al., 2015). RNNs were also used for action recognition (Ng et al., 2015). RNNS were still perform whole video classification by using average pooling and does not consider the use of RNNs for prediction. In a very recent work, however, Ma et al. (2016) train a LSTM using novel ranking losses for early activity detection. Our contribution regarding action recognition is not that we introduce a new technique. We use an existing method (LSTM) and demonstrate it in an online prediction system. The system keeps predicting, and considers the prediction reliable, when the predicted label converges (i.e. stays the same over a number of frames). Furthermore, the subject of our study is novel. The previous approaches consider the classical full body action problem. Here our emphasis is specifically on the hand motion, not considering other information such as the objects involved.

3 Our Approach

In this section, we first review the basics of Recurrent Neural Networks (RNNs) and the Long Short Term Memory (LSTM) model. Then we describe the specific algorithms for prediction of actions and forces used in our approach.

3.1 Recurrent Neural Networks

Recurrent Neural Networks have long been used for modeling temporal sequences. The recurrent connections are feedback loops in the unfolded network, and because of these connections RNNs are suitable for modeling time series with strong nonlinear dynamics and long time correlations.

Given a sequence $x = \{x_1,x_2,\ldots,x_T\}$, a RNN computes a sequence of hidden states $h = \{h_1,h_2,\ldots,h_T\}$ and outputs $y = \{y_1,y_2,\ldots,y_T\}$ as follows:

$$h_t = \mathcal{H}(Wh_t x_t + Wh h_{t-1} + b_h)$$

$$y_t = \mathcal{O}(W_h y_t + b_y),$$

where $W_h, W_h, W_h$ denote weight matrices, $b_h, b_y$ denote the biases, and $\mathcal{H}(\cdot)$ and $\mathcal{O}(\cdot)$ are the activation functions of the hidden layer and the output layer, respectively. Typically, the activation functions are defined as logistic sigmoid functions.

The traditional RNN is hard to train due to the so called vanishing gradient problem, i.e. the weight updates computed via error backpropagation through time may become very small. The Long Short Term Memory model (Hochreiter and Schmidhuber, 1997) has been proposed as a solution to over come this problem. The LSTM architecture uses memory cells with gated access to store and output information, which alleviates the vanishing gradient problem in backpropagation over multiple time steps.

Specifically, in addition to the hidden state $h_t$, the LSTM also includes an input gate $i_t$, a forget gate $f_t$, an output gate $o_t$, and the memory cell $c_t$ (shown in Figure 2). The hidden layer and the additional gates and cells are updated as follows:

$$i_t = \sigma(W_i x_t + W_h h_{t-1} + W_c c_{t-1} + b_i)$$

$$f_t = \sigma(W_f x_t + W_h h_{t-1} + W_c c_{t-1} + b_f)$$

$$c_t = f_t c_{t-1} + i_t \tanh(W_c x_t + W_h h_{t-1} + b_c)$$

$$o_t = \sigma(W_o x_t + W_h h_{t-1} + W_c c_t + b_o)$$

$$h_t = o_t \tanh(c_t)$$
In this architecture, \(i_t\) and \(f_t\) are sigmoidal gating functions, and these two terms learn to control the portions of the current input and the previous memory that the LSTM takes into consideration for overwriting the previous state. Meanwhile, the output gate \(o_t\) controls how much of the memory should be transferred to the hidden state. These mechanisms allow LSTM networks to learn temporal dynamics with long time constants.

3.2 RNN for action prediction

In this section, we describe our proposed model for action prediction. We focus on manipulation actions where a person manipulates an object using a single hand. Given a video sequence of a manipulation action, the goal is to generate a sequence of belief distributions over the predicted actions while watching the video. Instead of assigning an action label to the whole sequence, we continuously update our prediction as frames of the video are processed.

**Visual representation:** The visual information most essential for manipulation actions comes from the pose and movement of the hands, while the body movements are less important. Therefore, we first track the hand using a mean-shift based tracker [Bradski, 1998], and use cropped image patches centered on the hand. In order to create abstract representations of image patches, we project each patch through a pre-trained CNN model (shown in Figure 3). This provides the feature vectors used as input to the RNN.

**Action prediction:** In our model, the LSTM is trained using as input a sequence of feature vectors \(x = \{x_1, x_2, \cdots, x_T\}\) and the action labels \(y \in [1, N]\). The hidden states and the memory cell values are updated according to equations (7). Then logistic regression is used to map the hidden states to the label space as follows:

\[
P(Y = i|h_t, W_u, b_u) = \text{softmax}(W_u h_t + b_u).
\]

Then the predicted action label is obtained as:

\[
\hat{y}_t = \arg\max_i P(Y = i|h_t, W_u, b_u).
\]

**Model learning:** We follow the common approach of training the model by minimizing the negative log-likelihood over the dataset \(\mathcal{D}\). The loss function is defined as

\[
l(\mathcal{D}, W, b) = -\sum_{i=0}^{\vert \mathcal{D} \vert} \log(P(Y = y(i)|x(i), W, b)),
\]

where \(W\) and \(b\) denote the weight matrix and the bias term. These parameters can be learnt using the stochastic gradient descent algorithm.

Since we aim for the ongoing prediction rather than a classification of the whole sequence, we do not perform a pooling over the sequences to generate the outputs. Each prediction is based only on the current frame and the current hidden state, which implicitly encodes information about the history. In practice, we achieve learning by performing backpropagation at each frame.

3.3 RNN for prediction of forces at the fingers

We use a model similar to the one above to predict the forces on the fingers from visual input. Given video sequences of actions, as well as simultaneously recorded sequences of force measurements (see Sec. 4.1), we reformulate the LSTM model, such that it predicts force estimates as close as possible to the ground truth values.

As before, we use as input to the LSTM features from pre-trained CNNs applied to image patches. In addition, the force measurements \(v = \{v_1, v_2, \cdots, v_T\}\), \(v_i \in \mathbb{R}^M\), are used as target values, where \(M\) is the number of force sensors attached to the hand. Then the forces are estimated as:

\[
\hat{v}_i = W_v h_t + b_v.
\]

To train the force estimation model, we define the loss function as the least squares distance between the estimated value and the ground truth, and minimize it over the training set using stochastic gradient descent as:

\[
l(\mathcal{D}, W, b) = \sum_{i=0}^{\vert \mathcal{D} \vert} \sum_{t=0}^{T} ||\hat{v}_i - v_i||^2_2
\]

\[
(12)
\]
4 Data collection

4.1 A device for capturing finger forces during manipulation actions

We made a force sensing device with four force sensors attached directly to four fingers: the thumb, the pointer, the middle and the ring finger (see Figure 4(a)). We omitted the small finger, as the forces on this finger are usually quite small and not consistent across subjects (as found also by (Pham et al. 2015)). We used the piezoresistive force sensors by Tekscan, with a documented accuracy (by the manufacturer) of ±3%. The sensors at the finger tips have a measurement range of 0 to 8.896 N (2 lb), with a round sensing area of 9.53 mm in diameter. The entire sensing area is treated as one single contact point.

The raw sensor outputs are voltages, from which we derived the forces perpendicular to the sensor surfaces as:

\[ F = 4.448 \times \left( C_1 \times \frac{V_{out}}{V_{in} - V_{out}} - C_2 \right), \]

where \( V_{out} \) is the sensor measurement. \( V_{in} \), \( C_1 \), and \( C_2 \) are fixed constants of the system. To remove environmental noise, we applied notch filtering to the raw data, which gave us clear and smooth force outputs (see Figure 5). The software, which we designed for the device, will be released as a ROS package, including data recording and force visualization modules.

4.2 Manipulation Datasets

Two datasets were collected. The first dataset contains videos of people performing dexterous actions on various objects. The focus was to have different actions (with significant variation) on the same object. This dataset was used to validate our approach of visual action prediction.

The second dataset contains simultaneously recorded video and force data streams, but it has fewer objects. It was used to evaluate our approach of hand force estimation.

Fig. 4 Illustration of the force-sensing device. (a) The sensors on four fingers; (b) The data collection.

Fig. 5 Force data collection. (a) The raw, unfiltered voltage signal from the fingertip force sensors. (b) The filtered force signal from the fingertip sensors.

4.2.1 Manipulation action dataset (MAD)

We asked five subjects to perform a number of actions with five objects, namely cup, stone, sponge, spoon, and knife. Each object was manipulated in five different actions with five repetitions, resulting in a total of 625 action samples. Table 1 lists all the object and action pairs considered in MAD.

Table 1 Object and Action pairs of MAD

| Object | Actions                  |
|--------|--------------------------|
| cup    | drink, pound, shake, move, pour |
| stone  | pound, move, play, grind, carve |
| sponge | squeeze, flip, wash, wipe, scratch |
| spoon  | scoop, stir, hit, eat, sprinkle |
| knife  | cut, chop, poke a hole, peel, spread |

Since our aim was to build a system that can predict the action as early as possible, we wanted to study the prediction performance during different phases in the action. To facilitate such studies, we labeled the time in the videos when the hand establishes contact with the objects, which we call the “touching point.”

4.2.2 Hand actions with force dataset (HAF)

To solve the problem of synchronization, we asked subjects to wear on their right hand the force sensing device, leave their left hand bare, and then perform with both hands the same action, with one hand mirroring the other (see Figure 4(b) for the setting). We recorded from five subjects performing different manipulation actions on four objects, as listed in Table 2. Each action was performed with five repetitions, resulting in a total of 500 sample sequences.

5 An experimental study with humans

We were interested in how humans perform in prediction at different phases during the action. Intuitively, we would expect that the hand configuration and motion just before
| Object | Actions                      |
|--------|------------------------------|
| cup    | drink, move, pound, pour, shake |
| fork   | eat, poke a hole, pick, scratch, whisk |
| knife  | chop, cut, poke a hole, scratch, spread |
| sponge | flip, scratch, squeeze, wash, wipe |

Table 2  Object and Action pairs of HAF

the grasping of the object, when establishing contact, and shortly after the contact point can be very informative of the intended action. Therefore, in order to evaluate how early we can accurately predict, we investigated the prediction performance at certain time offsets with respect to the touching point.

We picked three objects from the MAD dataset for the study, namely cup, sponge and spoon. The prediction accuracy at four different time points was then evaluated: 10 frames before the contact point, exactly at contact, 10, and 25 frames after the contact point. Figure 6 shows the interface subjects used in this study.

![Fig. 6 Interface used in the human study.](image)

In a first experiment we asked 18 human subjects to perform the prediction task. For each of the three objects, after a short "training" phase in which all actions were demonstrated at full length, each subject was shown a set of 40 video segments and was asked to identify the currently perceived action. Each segment ended at one of the four time points relative to the contact point described above and was constructed from the same hand patches used in the computational experiments. All actions and all time offsets were equally represented. Figure 7(a) plots subjects’ average prediction performance for the different objects, actions and time offsets. With five actions per object, 20% accuracy corresponds to chance level. As we can see, the task of judging before and even at contact point, was very difficult and classification was at chance for two of the objects, the spoon and the cup, and above chance at contact only for the sponge. At 10 frames after contact human classification becomes better and reaches in average about 75% for the sponge, 60% for the cup, but only 40% for the spoon. At 25 frames subjects’ judgment becomes quite good with the sponge going above 95% for four of the five actions, and the other two actions in average at about 85%. We can also see which actions are easily confused. For the cup, ‘shake’ and ‘hit’ were even after 25 frames still difficult to recognize, and for the spoon the early phases of movement for most actions appeared similar, and ‘eat’ was most difficult to identify.

To see whether there is additional distinctive information in the actors’ movement, and subjects can take advantage of it with further learning, we performed a second study. Five participating subjects were shown 4 sets of 40 videos for each object, and this time they were given feedback on which was the correct action. Figure 7(b) shows the overall success rate for each object and time offset over the four sets. If learning occurs, subjects’ should improve from the first to the fourth set. The graphs show that there is a bit of learning. The effect is largest for the spoon, where subjects can learn to better distinguish at 10 frames after contact. The focus was to have different actions (with significant variation) on the same object.

![Fig. 7 Human prediction performance. (a) First study (without feedback). Success rate for three objects (cup, sponge, and spoon) for five different actions at four time offsets. (b) Second study (with feedback). Success rate for three objects averaged over five actions over four sets of videos at four offsets.](image)

6 Experimental results

The two algorithms have been implemented in a system that runs in real-time on a GPU. This sections reports three ex-
Fig. 8 Prediction accuracies over time for the five different objects, and Prediction Uncertainty computed from the entropy. The black vertical bars show the touching point. For each object we warped and aligned all the sample sequences so that they align at the same touching point. Best viewed in color.

Experimental evaluations. The first experiment evaluates the prediction performance as an on-going task, the second compares our action recognition algorithm against human performance, and the third evaluates our force estimation.

6.1 Hand action prediction on MAD

Our approach uses visual features obtained with deep learning, which serve as input to a sequence learning technique.

First we apply the mean-shift based tracker of Comaniciu et al (2000) to obtain the locations of the hand. We crop image patches of size 224 × 224 pixels, centered on the hand. Then our feature vectors are computed by projecting these patches through a convolutional neural network. To be specific, we employ the VGG network (Simonyan and Zisserman, 2014b) with 16 layers, which has been pre-trained on the ImageNet. We take the output of layer “fc7” as feature vector (4096 dimensions), which we then use to train a one layer LSTM RNN model for action prediction.

Our RNN has hidden states of 64 dimensions, with all the weight matrices randomly initialized using the normal distribution. We first learn a linear projection to map the 4096 input features to the 64 dimensions of the RNN. We use mini-batches of 10 samples and the adaptive learning rate method to update the parameters. The training stops after 100 epochs in all the experiments.

To evaluate the action prediction performance, we performed leave-one-subject-out cross-validation over the five subjects. Each time we used the data from one subject for testing, and trained the model on the other four subjects. Then all the results were averaged over the five rounds of testing.

6.1.1 On-going prediction

Our goal is to understand how the recognition of action improves over time. Thus, we plot the prediction accuracy as a function of time, from the action preparation to the end of the action. Our system performs predictions based on every new incoming frame as the action unfolds.

The first five plots in Figure 8 show the change in prediction accuracy over time. For a given action video, our system generates for each frame a potential score vector (with one value for each action) to form a score sequence of same length as the input video. Since the actions have different length, we aligned them at the touching points. To be specific, we resampled the sequences before and after the touching points to the same length. For each object, we show the prediction accuracy curves of the five actions.

The vertical bar in each figure indicates the time of the touching point. The touching point splits the sequence into two phases: the “preparation” and the “execution”. It is interesting to see that for some object-action pairs our system yields high prediction accuracy even before the touching point, e.g. the “cup - drink” and “sponge - wash”.

The last plot in Figure 8 shows the change of prediction uncertainty over time for each of the five objects. This measure was derived from the entropy over the different actions. As can be seen, in all cases, the uncertainty drops rapidly as the prediction accuracy rises along time.
6.1.2 Classification results

At the end of the action, the on-going prediction task becomes a traditional classification. To allow evaluating our method on classical action recognition, we also computed the classification results for the whole video. The estimate over the sequence was derived as a weighted average over all frames using a linear weighting with largest value at the last frame. To be consistent with the above, the classification was performed for each object over the five actions considered.

Figure 9 shows the confusion matrix of the action classification results. One can see that, our model achieved high accuracy on various object-action combinations, such as "cup/drink" and "sponge/wash", where the precision exceeds 90%.

We used two traditional classification methods as our baseline: Support Vector Machine (SVM) and Hidden Markov Model (HMM). For the HMM model, we used the mixture of Gaussian assumption and we chose the number of hidden states as five. Since the SVM model doesn’t accept input samples of different length, we used a sliding window (size = 36) mechanism. We performed the classification over each window, and then combined the results using majority voting. For both these baseline methods, we conducted a dimension reduction step to map the input feature vectors to 128 dimensions using PCA. To further explore the efficiency of the LSTM method in predicting actions on our dataset, we also applied the LSTM model using HoG features as input. The average accuracy was found 59.2%, which is 10% higher than the HMM and 23% higher than the SVM, but still significantly lower than our proposed method.

6.1.3 Discussion

It should be noted that this is a novel, challenging dataset with no equivalent publicly available counterparts. Subjects performed the action in unconstrained conditions, and thus there was a lot of variation in their movement, and they performed some of the actions in very similar ways, making them difficult to distinguish, as also our human study confirms.

The results demonstrate that deep learning based continuous recognition of manipulation actions is feasible, providing a promising alternative to traditional methods such as HMM, SVM and other methods based on hand-crafted features.

6.2 Action prediction at the point of contact, before and after

We next compare the performance of our online algorithm (as evaluated in Section 6.1.1) against those of human subjects. Figure 10 summarizes the prediction performance per object and time offset. As we can see our algorithm’s performance is not significantly behind those of humans. At ten frames after contact, computer lags behind human performance. However, at 25 frames after the contact point, the gaps between our proposed model and human subjects are fairly small. Our model performs worse on the spoon, but this is likely due to the large variation in the way different people move this object. Our human study already revealed
the difficulty in judging spoon actions, but the videos shown to subjects featured less actors than were tested with the algorithm. Considering this, we can conclude that our algorithm is already close to human performance in fast action prediction.

Fig. 10 Comparison of prediction accuracies between our computational method (C) and data from human observers (H). Actions are classified at four different time points before, at, and after the touching point (at -10, 0, +10, +25 frames from the touching point). C denotes the learnt model, H denotes the psychophysical data).

6.3 Hand force estimation on HAF

In the following we demonstrate the ability of the RNN to predict the forces on the fingers directly from images. We developed an online force estimation system. While watching a person performing actions in front of the camera, our system provides the finger forces in real time. Figure 11 shows one example of online force prediction for the “drink” action. We next describe our training method, and then present our results.

6.3.1 Training

The LSTM model (described in Section 3.3) is used to estimate the hand forces for each frame. Since people have different preferences in performing actions, the absolute force values can vary significantly for the same action. Therefore, we first normalize the force samples, which are used for training, to the range [0, 1]. The visual features in the video frames are obtained the same way as in the action prediction. Our LSTM model has one layer with 128 hidden states. To effectively train the model, we use the adaptive learning rate method for updating the neural network, and we use a batch size of 10 and stop the training at 100 epochs.

6.3.2 Results

We first show examples of our force estimation and then report the average errors. Figure 12 shows sample results. For each of the six pairs, the upper graph shows the estimated forces, and the lower one shows the ground truth. It can be seen that our system estimates well the overall force patterns for different actions. For example, for the “sponge/squeeze” action, the estimated forces correctly reproduce the three peaks of the real action, or for the “cup/move” action, the output forces predict the much smoother changes. Table 4 provides the average error of estimated force for each finger, and Table 5 gives the average estimation error for all the actions. The errors are in the range of 0.075 to 0.155, which demonstrates that the method also has good quantitative prediction and potential for visual force prediction.

Table 4 Average errors of estimated force for each finger

| Finger | Avg. | Ring | Middle | Pointer | Thumb |
|--------|------|------|--------|---------|-------|
|        |      | 0.103| 0.098  | 0.130   | 0.119 |

Table 5 Average errors of estimated force for each action

| Object | Action 1 | Action 2 | Action 3 | Action 4 | Action 5 |
|--------|----------|----------|----------|----------|----------|
| Cup    | Drink    | Move     | Pound    | Pour     | Shake    |
|        | 0.096    | 0.122    | 0.108    | 0.107    | 0.110    |
| Fork   | Eat      | Hole     | Pick     | Scratch  | Whisk    |
|        | 0.106    | 0.090    | 0.075    | 0.094    | 0.100    |
| Knife  | Chop     | Cut      | Poke     | Scratch  | Spread   |
|        | 0.157    | 0.155    | 0.109    | 0.123    | 0.110    |
| Sponge | Flip     | Scratch  | Squeeze  | Wash     | Wipe     |
|        | 0.101    | 0.130    | 0.112    | 0.127    | 0.121    |
Fig. 12 Samples of force estimation results. The first and third row show the force estimation. The second and fourth row show the corresponding ground truth values.

| Object | cup | stone | sponge | spoon | knife | Avg. |
|--------|-----|-------|--------|-------|-------|------|
| Vision | 82.4% | 61.4% | 61.6% | 62.6% | 73.3% | 68.3% |
| V+F    | 88.2% | 75.1% | 59.1% | 57.5% | 72.7% | 70.5% |

Table 6 Action prediction accuracy. Comparison of prediction using vision data only (“Vision”) against using vision and force data (“V+F”).

6.3.3 Why predict forces?

One motivation for predicting forces, is that the additional data, which we learned through association, may help increase recognition accuracy. There is evidence that human understand others’ actions in terms of their own motor primitives (Gallesse and Goldman, 1998; Rizzolatti et al., 2001). However, so far these findings have not been modeled in computational terms.

To evaluate the usefulness of the predicted forces, we applied our force estimation algorithm on the MAF dataset to compute the force values. Then we used the vision data together with the regressed force values as bimodal information to train a network for action prediction. Table 6 shows the results of the prediction accuracy with the bimodal information on different objects. Referring to the table, the overall average accuracy for the combined vision force data (V+F) was 2.2% higher than for vision information only.

This first attempt on predicting with bimodal data demonstrates the potential of utilizing visually estimated forces for recognition. Future work will further elaborate on the idea and explore networks (Hoffman et al., 2016), which can be trained from both vision and force at the same time to learn “hallucinate” the forces and predict actions.

As discussed in the introduction, the other advantage is that we will be able to teach robots through video demonstration. If we can predict forces exerted by the human demonstrator and provide the force profile of the task using vision only, this would have a huge impact on the way robots learn force interaction tasks. In future work we plan to develop and employ sensors that can also measure the tangential forces, i.e. the frictions, on the fingers. We also will expand the sensor coverage to the whole hand. With these two improvements, our method could be applied to a range of complicated tasks such as screwing or assembling.

7 Conclusion and Future work

In this paper we proposed an approach to action interpretation, which treats the problem as a continuous updating of beliefs and predictions. The ideas were implemented for two tasks: the prediction of perceived action from visual input, and the prediction of force values on the hand. The methods were shown to run in real-time and demonstrated high accuracy performance. The action prediction was evaluated
also against human performance, and shown to be nearly on par. Additionally, new datasets of videos of dexterous actions and force measurements were created, which can be accessed from [Fermüller 2016].

The methods presented here are only a first implementation of a concept that can be further developed along a number of directions. Here, we applied learning on 2D images only, and clearly, this way we also learn properties of the images that are not relevant to the task, such as the background textures. In order to become robust to these ‘nuisances’, 3D information, such as contours and depth features, could be considered in future work. While the current implementation only considers action labels, the same framework can be applied for other aspects of action understanding. For example, one can describe the different phases of actions and predict these sub-actions since different actions share similar small movements. One can also describe the movements of other body parts, e.g., the arms and shoulders. Finally, the predicted forces may be used for learning how to perform actions on the robot. Future work will attempt to map the forces from the human hands onto other actuators, for example three-fingered hands or grippers.
